ABSTRACT

The most abundant green tea polyphenol, epigallocatechin-3-gallate (EGCG), was found to induce differential effects between tumor cells and normal cells. Nevertheless, how normal epithelial cells respond to the polyphenol at concentrations for which tumor cells undergo apoptosis is undefined. The current study tested exponentially growing and aged primary human epidermal keratinocytes in response to EGCG or a mixture of the four major green tea polyphenols. EGCG elicited cell differentiation with associated induction of p57/KIP2 within 24 h in growing keratinocytes, measured by the expression of keratin 1, filaggrin, and transglutaminase activity. Aged keratinocytes, which exhibited low basal cellular activities after culturing in growth medium for up to 25 days, renewed DNA synthesis and activated succinate dehydrogenase up to 37-fold upon exposure to either EGCG or the polyphenols. These results suggest that tea polyphenols may be used for treatment of wounds or certain skin conditions characterized by altered cellular activities or metabolism.

Green tea polyphenols (referred to as GTPPs, to include the four major polyphenols: epicatechin, epigallocatechin, epicatechin-3-gallate, and epigallocatechin-3-gallate (EGCG) have been identified to possess chemopreventive and apoptotic activity against certain cancers, whereas normal epidermal keratinocytes follow a survival pathway that has not been fully elucidated (Chen et al., 1998; Paschka et al., 1998; Kuroda and Hara, 1999; Mukhtar and Ahmad, 1999; Mukhtar and Ahmad, 2000; Ahmad and Mukhtar, 2001; Hsu et al., 2001, 2002a,b, 2003). The most abundant green tea polyphenol, EGCG, was reported to induce differentiation and decreased cell proliferation in epidermal keratinocytes (Balasubramanian et al., 2002), rather than apoptosis as it does in tumor cells (Paschka et al., 1998; Hsu et al., 2001, 2002a, 2003).

We previously reported that both GTPPs and EGCG were able to induce transient expression of p57/KIP2, a differentiation/cell cycle regulator, which was associated with cell survival during GTPP exposure (Hsu et al., 2001). It was proposed that p57 induction may stimulate cell differentiation as part of a survival pathway (Hsu et al., 2001, 2002a,b). Although this survival pathway is currently under investigation, the impact of GTPPs on epidermal keratinocytes located in various layers of the skin was deemed essential to be addressed, given the fact that GTPPs are able to penetrate the epidermis, but not the dermis, of human skin (Dvorakova et al., 1999).

Keratinocytes within the epidermis exist in various stages of differentiation corresponding to different epidermal layers (Bikle et al., 2001; Bollag and Bollag, 2001). For example, the basal keratinocytes and/or stem cells at the dermal-epidermal junction continuously proliferate to regenerate and restore cells lost to the environment. As the daughter cells migrate up through the epidermal layers, they first undergo growth arrest followed by expression of keratins 1 and 10 in the spinous layer. In the next layer, the granular layer, late markers of keratinocyte differentiation, including filaggrin and other structural proteins, are expressed. In addition, the activity of transglutaminase, the enzyme that cross-links the structural proteins into the cornified envelope, is increased. Finally, the keratinocytes undergo an epidermal-specific programmed cell death to form the cornified layer, which serves as a barrier to mechanical injury, microbial invasion, and water loss. The entire epidermis turns over in 1 to 2 months, although the transit time of keratinocytes may be lengthened or shortened in various disease states. We considered it per-
tient to investigate whether GTPPs induce differential effects among keratinocytes at different stages of differentiation and/or age, knowing that if so, such effects could be significant for assessing the potential impact of these compounds upon topical application. Thus, agents that accelerate growth and/or differentiation of epidermal keratinocytes may shorten the healing time of certain wounds and serve as treatments for certain epidermal-skin diseases.

We hypothesized that green tea polyphenols, either in a mixture or in the form of purified EGCG, are able to increase cellular activities, including new DNA synthesis, in aged keratinocytes, or promote differentiation of exponentially growing keratinocytes located in the basal layer of epidermis. Therefore, the current study examined pooled normal human primary epidermal keratinocytes treated with EGCG or GTPPs after various times of culture. Results from this study demonstrated that 1) by promoting biological energy production and new DNA synthesis, both EGCG and GTPPs “reenergized” the aged keratinocytes; thus, these compounds can presumably stimulate the regeneration of keratinocytes in aging skin; and 2) by induction of p57, keratin 1 and filaggrin expression, and activation of transglutaminase, EGCG also stimulated the differentiation of the keratinocytes found in the basal layer of the epidermis. The combination of these two effects may help to accelerate wound healing and regeneration of new skin tissue, and subsequently prevent scar tissue formation. In addition, certain epithelial conditions may be amenable to treatment by topical applications of green tea polyphenols.

Materials and Methods

Chemicals and Antibodies. EGCG was purchased from Sigma-Aldrich (St. Louis, MO). A mixture of four major GTPPs was purchased from LKT Lab, Inc. (Minneapolis, MN). GTPPs and EGCG were dissolved in keratinocyte growth medium-2 (KGM-2; BioWhittaker, East Rutherford, NJ) and filter-sterilized immediately before use. The rabbit anti-human p57 antibody C-19 was purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA); the rabbit anti-filaggrin and anti-keratin-1 antibodies were from Covance (Berkeley, CA).

Culturing Normal Human Epithelial Cells. The pooled normal human primary epidermal keratinocytes were purchased from BioWhittaker and subcultured in the specific growth media provided by the manufacturer (KGM-2). Subculture of the epithelial cells was performed by detaching the cells in 0.025% trypsin and transferring to tissue culture plates before EGCG exposure. The cells were scraped from the plates with a rubber policeman and transferred to new tissue culture flasks at the recommended density of 3500 cells/cm². Exponentially growing keratinocytes were treated and harvested in their early passages (2–3 passages). Aged keratinocytes were allowed to grow in 96-well tissue culture plates for 15, 20, and 25 days before treatment by EGCG or GTPPs, followed by various assays.

3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl Tetrazolium Bromide (MTT) Assay. In a 96-well plate, cells were seeded at 1.5 × 10⁴ cells/well. After 24-h treatment, culture medium was removed and replaced with 100 μl of 2% MTT in a solution of 0.05 M Tris, 0.5 mM MgCl₂, 2.5 mM CoCl₂, and 0.25 M disodium succinate (Sigma-Aldrich), and the plate was incubated at 37°C for 30 min. The MTT solution contains only disodium succinate as a substrate; therefore, this method directly detects the activity of mitochondrial succinate dehydrogenase (SDH). Cells were fixed in situ by the addition of 100 μl of 4% formalin in 0.2 M Tris (pH 7.7), and after a 5-min incubation at room temperature liquid was removed and the wells were allowed to dry. Each well was rinsed with 200 μl of water, and cells were solubilized by the addition of 100 μl of 6.35% 0.1 N NaOH in dimethyl sulfoxide. The colored formazan product was measured by a Thermo MAX microplate reader (Molecular Devices Corp., Sunnyvale, CA) at a wavelength of 562 nm. Experiments were repeated three times with triplicate samples for each experiment.

Analysis of DNA Synthesis Using the BrdU Incorporation Method. The BrdU cell proliferation kit was purchased from Oncogene Research Products (Boston, MA). Cells were cultured in 96-well plates at the density of 10⁴ cells/well. After EGCG and GTPPs treatments, cells were labeled with BrdU for 12 h, and levels of BrdU incorporation were determined according to the manufacturer's instructions using a Thermo Max microplate reader at a wavelength of 450 nm and subtracting absorbance measured at 540 nm. Experiments were repeated three times in triplicate for each experiment.

Immunocytochemistry. Normal human keratinocytes were seeded in eight-well chamber slides (Nagle Nunc International, Naperville, IL) 12 h before EGCG treatment. At the end of a 24-h treatment, the slides were washed with phosphate-buffered saline and fixed in a cold 4% paraformaldehyde solution for 10 min. Then 3% hydrogen peroxide solution and normal goat serum were applied to block endogenous peroxidase activity and nonspecific binding. The primary antibodies, rabbit anti-human p57 polyclonal antibody C-19, rabbit anti-human keratin 1, and filaggrin antibodies were applied for 1 h at 37°C at the dilutions recommended by the manufacturers. The streptavidin detection technique (Biogenex, San Ramon, CA) was used with 3-amino-9-ethylcarbazole as chromogen. Negative control sections consisted of cells treated with 1% diluted normal goat serum instead of primary antibody. Mayer's hematoxylin was used as a counterstain.

Transglutaminase Activity Assay. Normal human epidermal keratinocytes in early passages were allowed to grow in six-well tissue culture plates before EGCG exposure. The cells were scraped in homogenization buffer (0.1 M Tris/acetate, pH 8.5, containing 0.2 mM EDTA, 20 μM 4-(2-aminoethyl)benzenesulfonyl fluoride, 2 μg/ml aprotinin, 2 μM leupeptin, and 1 μM pepstatin A), collected by centrifugation, and subjected to one freeze-thaw cycle before lysis by sonication. Unlysed cells were pelleted by centrifugation and aliquots of the supernatant collected for the determination of transglutaminase activity and protein concentration. Protein quantities were determined using the Bio-Rad protein assay (Bio-Rad, Hercules, CA) with bovine serum albumin as standard. Transglutaminase activity was measured as the incorporation of [1H]putrescine into dimethyl- cased amine, as described previously (Jung et al., 1998).

Caspase 3 Activity Assay. The caspase 3 apoptosis detection kit was purchased from Santa Cruz Biotechnology, Inc. Cells (10⁵/well) were plated in triplicate in a 24-well tissue culture plate. After 24-h treatments with EGCG or GTPPs, the cells in each well were washed with 1 ml of phosphate-buffered saline and incubated with 100 μl of lysis buffer on ice for 10 min. To each well, 100 μl of 2× reaction buffer was added with 10 mM dithiothreitol. Finally, 5 μl of DEVD- AFC substrate was added to each well containing cell lysates. The reaction mixtures were incubated for 1 h at 37°C, and caspase 3 activity in each well was measured using a fluorescence microplate reader at a wavelength of 405 nm for excitation and 505 nm for emission.

Results

Unlike a variety of tumor cell lines tested, normal human epidermal keratinocytes are able to survive when exposed to EGCG or GTPPs (Chen et al., 1998; Mukhtar and Ahmad, 1999; Suganuma et al., 1999; Hsu et al., 2001; Jin et al., 2001; Nie et al., 2002). Therefore, we examined the effect of EGCG and GTPPs on markers of cell status, such as apoptosis, proliferation, differentiation, and energy production. In initial experiments, exponentially growing keratinocytes were exposed to these agents. As shown in Fig. 1, there was no effect of EGCG or GTPPs on caspase 3 activity, a measure of
apoptosis. There was also little or no effect of these compounds on BrdU incorporation into DNA (Fig. 1), a measure of proliferative status, or on energy production, as measured by changes in the mitochondrial enzyme SDH activity monitored by the MTT assay (Fig. 1).

Treatment with EGCG was observed to induce changes in cell morphology as shown in Fig. 2. Thus, EGCG increased the number of enlarged, flattened, squame-like cells observed in these cultures (Fig. 3B). This morphology is typical of differentiated keratinocytes, suggesting an ability of EGCG to trigger cell differentiation. Further confirmation of this capacity of EGCG to induce keratinocyte differentiation is provided by the results shown in Fig. 2C. These data demonstrate that in exponentially growing keratinocytes EGCG was also able to increase, by up to 500%, transglutaminase activity, a characteristic of late-stage keratinocyte differentiation.

Our previous results suggested that in keratinocytes EGCG- and GTPP-mediated induction of the expression of a cell cycle inhibitor p57 allowed survival of these cells upon exposure to the polyphenols (Hsu et al., 2001, 2002b). Therefore, we examined the effect of EGCG and GTPPs on p57 expression in exponentially growing keratinocytes. Figure 3B shows that EGCG induced p57 expression in these cells. In addition, EGCG enhanced the expression of an early keratinocyte differentiation marker, keratin 1 (Fig. 3D), as well as a late marker, filaggrin (Fig. 3F), suggesting that this agent had the capacity to induce multiple stages of keratinocyte differentiation.

Because responses of aged keratinocytes may differ from those of exponentially growing keratinocytes, we also investigated the effect of EGCG and GTPPs on keratinocytes that were no longer in an exponential growth phase. After 15, 20, or 25 days in culture, the pooled primary human epidermal keratinocytes gradually lost their ability to either generate ATP or divide. At these time points, EGCG or GTPPs were able to activate SDH, as measured by the MTT assay (Fig. 4A, C, and E), up to 37-fold (25 days, Fig. 4E). The activation of this component of the tricarboxylic acid cycle may provide biological energy and substrates for other responses such as new DNA synthesis. When aged human keratinocytes lost the ability to synthesize new DNA, especially after 20+ days in KGM-2, both EGCG and GTPPs were able to stimulate new DNA synthesis, as measured by BrdU incorporation into DNA (Fig. 4, B, D, and F), up to approximately 3-fold (25 days, Fig. 4F). To our knowledge, this represents the first observation that green tea components stimulate energy generation in aged epidermal keratinocytes. On the other hand, it was noted that for the aged keratinocytes at the 15- and 20-day time points, lower concentrations of EGCG (15–50 μM) had a slight negative impact on BrdU incorporation (Fig. 4, B and D). Nevertheless, EGCG concentrations higher than 100 μM consistently induced both SDH activity and BrdU incorporation (Fig. 4).

Discussion

Previous reports describing growth arrest and differentiation of exponentially growing keratinocytes indicated that EGCG enhanced the expression of involucrin and increased the conversion of undifferentiated keratinocytes into corneoocytes with concomitant decreased cell proliferation (Balasubramanian et al., 2002). The current study further confirmed that undifferentiated keratinocytes were able to commit to differentiation upon EGCG treatment within a short period, accompanied by an elevation in the activity of transglutaminase, the enzyme that cross-links involucrin and other substrates to form the cornified envelope (Bikle et al., 2001).
When exponentially growing pooled normal human primary epidermal keratinocytes were incubated with 50 to 100 μM EGCG for 24 h and stained with antibody specific for human p57, these cells were treated with 100 μM EGCG and stained with antibody specific for human keratin 1. F, cells were treated with 100 μM EGCG and stained with antibody specific for human filagrin. In all panels, EGCG was shown to induce changes in cell morphology, increasing the number of enlarged, flattened, squame-like keratinocytes observed in the cultures. These cell characteristics are typical of differentiated keratinocytes, as indicated also by the enhanced expression of differentiation markers in these squamous cells. Original magnification, 400×. Experiments were repeated twice with similar results.

Fig. 3. EGCG and GTPPs increase levels of differentiation markers in exponentially growing keratinocytes. A, C, and E, untreated cells. B, cells were treated with 100 μM EGCG for 24 h and stained with antibody specific for human p57. D, cells were treated with 100 μM EGCG and stained with antibody specific for human filagrin. F, cells were treated with 100 μM EGCG and stained with antibody specific for human keratin 1. F, cells were treated with 100 μM EGCG and stained with antibody specific for human filagrin. In all panels, EGCG was shown to induce changes in cell morphology, increasing the number of enlarged, flattened, squame-like keratinocytes observed in the cultures. These cell characteristics are typical of differentiated keratinocytes, as indicated also by the enhanced expression of differentiation markers in these squamous cells. Original magnification, 400×. Experiments were repeated twice with similar results.

Fig. 4. EGCG and GTPPs stimulate mitochondrial energy production and DNA synthesis in aged keratinocytes. A, C, and E, results of MTT assays in normal human primary epidermal keratinocytes cultured for 15, 20, or 25 days in KGM-2 medium, respectively, and treated with increasing concentrations of EGCG as indicated, or 0.2 mg/ml GTPPs for 24 h. Data represent the average and standard deviation of triplicate samples with *, p < 0.05 and **, p < 0.001 versus the control value. Experiments were repeated five times with consistent results. B, D, and F, BrdU assay results of normal human primary epidermal keratinocytes cultured for 15, 20, and 25 days in KGM-2 medium, respectively, and treated with increasing concentrations of EGCG as indicated or 0.2 mg/ml GTPPs for 24 h. Data represent the average and standard deviation of triplicate samples with *, p < 0.01 and **, p < 0.001 versus the control value. Experiments were repeated three times with consistent results, and the experiments were performed in parallel.

30 days failed to induce dermal toxicity (Stratton et al., 2000). In addition, the viability of the keratinocytes was confirmed by BrdU incorporation and SDH activity upon EGCG or GTPP exposure, and their apoptotic status investigated by a caspase 3 activity assay; and there was no major alteration in these measurements (Fig. 1). In contrast, this same concentration range has been applied to tumor cell cultures and induced apoptotic effects (Suganum et al., 1999; Chen et al., 2000; Jin et al., 2001; Yokoyama et al., 2001; Nakagawa et al., 2002; Nie et al., 2002). This evidence suggests that the effect of EGCG on exponentially growing keratinocytes is a selective induction of differentiation, in contrast to the apoptotic cell death initiated in tumor cells.

It has been suggested that H₂O₂ produced by EGCG in cell culture is an important factor for tumor cell death (Sakagami et al., 2001). At concentrations above 50 μM, EGCG is able to produce considerable amounts of H₂O₂ and form oxidized products in cell culture that may interfere with MTT assays (Hong et al., 2002). We found that incubation of keratinocytes...
with \( H_2O_2 \) concentrations reported to be induced by EGCG for time periods that paralleled those of Hong’s study did not influence the MTT assay under our experimental conditions. Likewise, MTT assay results were not significantly higher at the 4-h EGCG treatment time point (data not shown), when the oxidized products of EGCG peak (Hong et al., 2002). In addition, MTT assays were carried out with or without MTT/sodium succinate, the results indicated that EGCG and/or its oxidized forms do not play a significant role in 562 nm absorption in our system (data not shown).

Results in Figs. 2 and 3 indicated that EGCG induced differentiation in exponentially growing keratinocytes, whereas those in Fig. 4 suggested that in aged keratinocytes the effect of EGCG and GTPPs was to stimulate proliferation and accelerate tricarboxylic acid cycle that supplies reducing equivalents for biological energy production. Therefore, the age of the keratinocytes and the concentration of EGCG or GTPPs used are two key factors in terms of the effects of these agents on differentiation, energy generation, and DNA replication. Of interest is the relationship of aged cultures of keratinocytes to their differentiation status. Because human keratinocytes are prone to undergo growth arrest and to express differentiation markers upon attaining confluence (Lee et al., 1998), we predict that the response of keratinocytes in upper epidermal layers will mirror that of the aged keratinocytes. Thus, we propose that EGCG and the GTPPs will stimulate reentry into the cell cycle in the early differentiated (spinous) stratum of the skin. A study by Fu et al. (2000) also suggests a protective effect of GTPPs on rat keratinocytes, such that these authors observed a decrease in an apoptotic marker (lactate dehydrogenase release) as well as an increase in keratinocyte proliferation as measured by cell counting, flow cytometry, and proliferative index. Additional protective effects of GTPPs are also indicated by their ability to act as antioxidants and decrease lipid peroxidation products and increase glutathione peroxidase levels (Fu et al., 2000); and their ability to protect the epidermis from carcinogen-induced tumorigenesis or chemically induced inflammation (Huang et al., 1992).

Thus, we report here for the first time, that at certain concentrations, EGCG or a mixture of the major green tea polyphenols stimulated aged keratinocytes to generate biological energy and to synthesize DNA, possibly for renewed cell division. For keratinocytes in an exponential growth phase, EGCG potently stimulated these cells to commit to differentiation with minimal impact on DNA synthesis or energy levels during a 24-h period. We speculate that by stimulating differentiation of keratinocytes in the basal layer of the epidermis and energizing and stimulating cell division/DNA synthesis in aged suprabasal keratinocytes, these compounds could potentially reduce the time of healing and prevent the formation of scar tissue, which occupies the space not repopulated by keratinocytes. Therefore, green tea constituents may be useful topically for promoting skin regeneration, wound healing, or treatment of certain epithelial conditions such as aphthous ulcers, psoriasis, rosacea, and actinic keratosis. In addition, the differentiation-inducing potential of green tea components might be beneficial to patients who have conditions characterized by abnormally accelerated skin cell growth and lack of differentiation. However, future studies are needed to determine the optimal time of treatment, concentrations, and combinations of green tea polyphenols to be used topically for therapeutic intervention in various epithelial conditions.
