Received June 2, 2005; accepted August 30, 2005

ABSTRACT

Although buprenorphine is used worldwide as a safe and effective maintenance medication for opioid dependence, some countries have reported a growing incidence of abuse of this medication. Buprenorphine is considered to have lower abuse potential because of its partial agonist profile, but no studies have directly compared the reinforcing effects of buprenorphine with those of full \( \mu \) opioid agonists in humans. The present double-blind, placebo-controlled inpatient study compared the reinforcing and subjective effects of intravenously administered buprenorphine (0.5, 2, and 8 mg) and methadone (5, 10, and 20 mg). Participants (n = 6) were detoxified from heroin during the first 1 to 2 weeks after admission. During subsequent weeks, participants received a sample drug dose and $20 on Monday, and they could self-administer either the sampled dose or $20 during one choice session per day on Thursday and Friday. Participants responded under a modified progressive ratio schedule during each choice session. All active doses maintained higher progressive ratio break points (largest completed ratio) than placebo. There were no significant differences in break point values between buprenorphine and methadone or among the different doses of drug. However, several subjective ratings, including “good drug effect”, “high”, and “liking” dose-dependently increased after administration of buprenorphine and methadone. The peak ratings for these effects did not significantly differ for the two drugs. These results demonstrate that under these experimental conditions, buprenorphine and methadone were equally effective in producing reinforcing and subjective effects.

Buprenorphine, a partial \( \mu \) opioid agonist and \( \kappa \) opioid antagonist, is used clinically to treat pain, and more recently, it has been used as a safe and effective maintenance therapy for opioid dependence. The partial agonist profile of buprenorphine was defined by several studies conducted in both laboratory animals and humans showing that its effects are less robust than those of full \( \mu \) agonists, particularly when the intensity of the stimulus (e.g., pain intensity) is high. For example, in a warm water tail withdrawal procedure, buprenorphine produces maximal analgesic effects when the water temperature is low but not when it is high (Walker et al., 1995; Morgan et al., 1999; Barrett et al., 2001). Similarly, in a drug discrimination paradigm, buprenorphine consistently substitutes fully for other \( \mu \) agonists when the training dose is low (Preston and Bigelow, 2000) but not when it is high (Picker et al., 1993). The partial agonist profile of buprenorphine is also revealed under conditions of opioid tolerance: the effects of buprenorphine are reduced more than those of other \( \mu \) agonists in opioid-tolerant animals. For example, in rats chronically treated with buprenorphine, the analgesic effects of buprenorphine itself were reduced to a greater extent than the analgesic effects of other \( \mu \) agonists, such as etorphine or morphine (Paronis and Holtzman, 1992; Walker and Young, 2001). In rhesus monkeys trained to self-administer the \( \mu \) opioid agonist alfentanil, intravenously delivered buprenorphine maintained moderate rates of responding in nondependent animals, but responding was virtually eliminated when the animals were chronically treated with morphine (Winger and Woods, 2001). These studies and others demonstrate that, under some conditions, buprenorphine produces full effects, but under other conditions, it does not. Thus, the experimental conditions under which the effects of buprenorphine are measured are important to consider when evaluating its abuse liability.

In a study comparing the effects of sublingual buprenorphine (0.5–32 mg) and oral methadone (3.75–60 mg) in opioid-abusing humans, Walsh et al. (1994, 1995) showed a

ABBREVIATIONS: SOWS, subjective opioid withdrawal scale; DEQ, drug effects questionnaire; SpO\(_2\), arterial blood oxygen saturation.
“ceiling” on the effects produced by buprenorphine but not methadone. An early study conducted by Jasinski et al. (1978) showed that subcutaneous buprenorphine (0.2–2 mg) produced dose-dependent increases in subjective effects that were comparable with those produced by morphine (15–40 mg) and methadone (30 mg). In that study, there was no evidence for a ceiling on the effects of buprenorphine, which may have been due to the relatively low doses of buprenorphine administered. A recent study by Umbricht et al. (2004) showed that high doses of intravenously administered buprenorphine (2–16 mg) produced dose-related increases in subjective effects, but due to large intersubject variability in response, these effects were not significantly different from placebo. In a study conducted in rhesus monkeys trained to self-administer opioids under progressive ratio schedules, Mello et al. (1988) showed that progressive ratio break point values for buprenorphine and methadone were comparable and that they were relatively low compared with heroin. No studies to date have directly compared both the reinforcing and subjective effects of buprenorphine with those of methadone, a full μ opioid agonist, in humans. The present study examined the abuse liability of high doses of intravenously delivered buprenorphine (0.5–8 mg) compared with methadone (5–20 mg) using a drug self-administration procedure that is designed to evaluate potential differences in reinforcing efficacy. The maximal doses were chosen to be those that would be safely tolerated in opioid-experienced, nondependent individuals. For methadone, studies have shown a roughly 2:1 ratio in steady-state plasma concentrations after oral and intravenous administration, respectively (Dale et al., 2004). Clinical experience suggests that substantial toxicity, including death, may occur in nonopioid-dependent individuals receiving a starting dose of 30 to 40 mg of methadone orally (Senay, 1999). Although a 30-mg subcutaneous dose of methadone has been administered safely to opioid-experienced, nondependent individuals (Jasinski et al., 1978), we opted to test a maximum dose of 20 mg of intravenous methadone to ensure safety. For buprenorphine, a maximal dose of 8 mg was also chosen for safety reasons. As described by Umbricht et al. (2004), a dose of 12 mg of intravenous buprenorphine produced severe nausea and vomiting in an opioid-experienced, nondependent individual. Our previous studies using 8 mg of intravenous buprenorphine showed that this dose was well tolerated, so we opted to use this maximum dose in the present study.

Materials and Methods

Participants
Six heroin-dependent individuals (five men, one woman; three Caucasian, two African-American, and one Hispanic), who currently were not seeking treatment for their drug use, completed the 8-week protocol. Participants were 39.5 ± 2.8 years of age on average (range 27–43 years) and reported using heroin for an average of 11.8 ± 3.7 years (range 3–24 years). Volunteers weighed 65.8 ± 2.4 kg and were 1.7 ± 0.9 m in height. All participants had experience using heroin by the intravenous route, were currently physiologically dependent on it as verified by a naloxone challenge test before admission, and reported spending an average of $62 ± 14 per day on heroin (range $20–100). Heroin was the drug of choice for all participants. Six individuals smoked tobacco cigarettes (15 ± 3 cigarettes per day), two participants used cocaine (once per month and twice per week or less), three participants used alcohol (one to two times per week or less), and one participant used marijuana (two per month). Three additional male participants (two Caucasian and one Hispanic) began the study but did not complete it. One participant was discharged early because he decided to seek treatment, one discontinued because he decided that he did not want to undergo detoxification, and one discontinued because he found the study procedures too boring.

After an initial telephone interview, eligible participants received additional screening that included completing detailed questionnaires on drug use, general health, and medical history and a medical and psychological evaluation. Participants were told that they would receive opioids during the study and that different doses would be tested. An electrocardiogram and Mantoux test or chest X-ray were also performed. Routine laboratory analyses included a hematology screen, blood chemistry panel, liver function tests, thyroid function tests, syphilis serology, and urinalysis. Urine drug toxicologies (opioids, benzoylcodeine, benzodiazepines, cannabinoids, and amphetamines) were also performed using a radiative energy attenuation and fluorescence polarization immunoassay system (ADx System; Abbott Laboratories, Abbott Park, IL).

Participants were excluded from the study if they were seeking drug treatment, dependent on alcohol or illicit drugs other than opioids, or had a major Axis I psychiatric diagnosis other than heroin dependence (e.g., bipolar disorder, schizophrenia, or major depression). Those who had recent histories of violence or who were on parole/probation were excluded from the study. Participants were required to be physically healthy and fully able to perform all study procedures.

Before admission, participants completed a training session, during which the study procedures were explained to them in detail. Volunteers were paid $25 per inpatient day and an additional $25 per day bonus if they completed the study. In addition, they could receive an additional $20 per experimental session. Participants signed consent forms describing the aims of the study and the potential risks and benefits of participation. Participants were offered free human immunodeficiency virus testing, drug and risk reduction education, and referrals for treatment. This study was approved by the Institutional Review Board of the New York State Psychiatric Institute.

Apparatus
During experimental sessions, participants were seated in a room equipped with Macintosh computers. All computer activities, vital signs, and behaviors were continuously monitored by the experimenters in an adjacent control room via a continuous online computer network, one-way mirror, and vital signs monitors (cardiovascular function was measured using a Sentry II vital signs monitor; NBS Medical, Costa Mesa, CA; and arterial oxygen saturation was measured using a pulse oximeter model 400; Palco Laboratories, Santa Cruz, CA). Communication between the staff and participants was kept to a minimum during experimental sessions.

Detoxification Procedures
Participants were detoxified during the first 1 to 2 weeks after their admission into the hospital. Buprenorphine (2–8 mg of sublingual tablet; National Institute on Drug Abuse, Rockville, MD) was administered during the first 2 days after admission. Clonidine HCl (0.2 mg p.o., every 6 h; Boehringer Ingelheim USA, Ridgefield, CT), ketorolac tromethamine (30 mg i.m., every 6 h for up to 5 days; F. Hoffman-La Roche, Nutley, NJ), prochlorperazine (10 mg p.o. or i.m., every 8 h; GlaxoSmithKline, Uxbridge, Middlesex, UK), and clonazepam (2 mg p.o., every 8 h; F. Hoffman-La Roche) were available, as needed. All of these medications were discontinued approximately 36 h before the first experimental session.

General Procedures
The reinforcing effects of intravenously delivered placebo, buprenorphine (0.5, 2, and 8 mg), and methadone (5, 10, and 20 mg)
were evaluated following detoxification. All doses were administered in nonsystematic order both within and between participants. On Mondays, a dose of drug and $20 was administered and subjective, performance, and physiological effects were examined both before and repeatedly after drug administration. These measures were repeated on Tuesdays (24 h) and Wednesdays (48 h) to assess the time course of the drug administered on Monday. No drugs were administered on Tuesdays and Wednesdays. On Thursdays and Fridays, participants completed one choice session per day for a total of two choice sessions. They could work to receive all or part of the dose or $20. The total amount of drug and/or money chosen during the self-administration task was given as a bolus at the end of the task.

Experimental Sessions

During all sessions, participants completed computerized tasks and subjective-effects questionnaires. Heart rate and blood pressure were measured every 5 min, and arterial blood saturation (SpO₂) was monitored continuously with a pulse oximeter and recorded every minute during experimental sessions. Pupil graphs were taken repeatedly during the session. Participants were not allowed to smoke tobacco cigarettes during experimental sessions.

Sample Session. Physiological, subjective, and performance effects were measured both before and repeatedly after drug administration. Following baseline measures, drug and $20 were administered simultaneously at time 0 min, provided that oxygenation was sufficient (SpO₂ > 93%). A photograph was taken of the right pupil before and 4, 10, 40, 60, 90, 120, and 180 min after drug administration. A subjective-effects battery was administered before and 4, 10, 60, 150, and 210 min after drug administration. A performance battery was administered before and 10, 60, 120, and 180 min after drug administration. The subjective opioid withdrawal scale (SOWS) was administered before and 180 min after drug administration. The drug effects questionnaire (DEQ) was administered 4, 10, 60, 120, and 180 min after drug administration.

No-Drug Sessions. Physiological, subjective, and performance effects were measured 24 and 48 h after administration of drug to evaluate potential long-lasting agonist effects.

Choice Sessions. Choice sessions were similar in design to the sample session, except that participants completed a self-administration task (see below) after the baseline assessments. Participants were instructed to choose between tens of $20 and the dose that they received during the sample session. A pupil photograph was taken before drug administration. The subjective-effects battery was administered before and 4 and 40 min after drug administration. The performance battery was completed before and 10 min after drug administration. The SOWS was completed before drug administration. The DEQ was completed before and 10 min after drug administration. Choice sessions were otherwise identical to the sample session.

Self-administration task. Participants were told that they could work for all or part of the sampled dose or the sampled money amount ($20) by choosing the drug or money option each time a choice was available. The alternative money value ($20) was chosen based on previous studies conducted in our laboratory (Comer et al., 1997, 1998) showing that the dose-response curve for heroin was the most lawful when this money value was used. Responses consisted of finger presses on a computer mouse. Standardized instructions were read to each participant explaining the self-administration task. Drug and money were available under independent progressive ratio schedules, and participants were given 10 opportunities (trials) to choose between the two options. Ten percent of that day’s dose or money value was available at each choice trial. Thus, if the dose for that day was 8 mg, at each opportunity participants could respond for 0.8 mg (10% of 8 mg) or $2 (10% of $20). Completion of the ratio requirement for each choice trial was accompanied by a visual stimulus on the computer screen. After a choice was made for one option, responding for the other option was not possible until the ratio was completed and another trial was initiated. The response requirement for each of the two options increased independently such that the initial ratio requirement for each option was 50 responses; the ratio increased progressively each time the option was selected (50, 100, 200, 400, 500, 1200, 1600, 2000, 2400, and 2800). To receive all of the drug or money available that day, participants were required to emit 11,550 responses within 40 min. Fewer total responses were required if choices were distributed between the two options. These ratio values were chosen based on previous research conducted in our laboratory (Comer et al., 1999). Although high rates of responding were required, participants were capable of completing 11,550 responses in the allotted time. For example, four of the six participants in the present study completed 11,550 responses on multiple occasions during the study.

At the start of each self-administration task, two illustrations were shown on the computer screen: an empty balance scale and an empty bank. As each choice trial was completed, either the scale was implemented with a pile of powder or a dollar sign was added to the bank. Thus, participants could always see how many money and drug choices had been made. At the end of the 40-min self-administration task, the participant received whatever he or she had chosen: money and/or drug.

Subjective measures. Four questionnaires were used to assess subjective effects (for details, see Comer et al., 1999). The first questionnaire was a 26-item visual analog scale designed to assess subjective and physiological effects. The 18 first lines were labeled with adjectives describing mood states (e.g., “I feel...” (high)) and four additional lines, labeled with questions about the dose just received (e.g., “I liked the dose,” “For this dose, I would pay”). Participants also indicated, by making a mark along a 100-mm line, how much they “wanted” each of the following drugs: heroin, cocaine, alcohol, and tobacco. Participants rated each item on the visual analog scale from “Not at all” (0 mm) to “Extremely” (100 mm), except for the “For this dose, I would pay” question, which ranged between $0 (0 mm) and $20 (100 mm). The second questionnaire was a 13-item opioid symptom checklist consisting of true-or-false questions designed to measure opioid effects (e.g., “My skin is itchy”). The visual analog scale and opioid symptom checklist together constituted the subjective-effects battery. The third questionnaire was the 16-item subjective opioid withdrawal scale. Participants rated each item on a scale from 0 to 4, with 0 being Not at all and 4 being Extremely (e.g., “I have gooseflesh”), etc. The fourth questionnaire was a six-item drug effects questionnaire. Participants described drug effects by selecting among a series of possible answers ranging from 0 (“No, good, bad, etc. effect at all”) to 4 (“Very strong effects”). Ratings of drug liking ranged between −4 (“Dislike very much”) and 4 (“Like very much”).

Task battery. The task battery consisted of four tasks: a 3-min digit-symbol substitution task, a 10-min divided attention task, a 10-min rapid information processing task, and a 3-min repeated acquisition of response sequences task (for details, see Comer et al., 1999). Briefly, the digit-symbol substitution task consisted of nine three-row by three-column squares (with one square blackened per row) displayed across the top of the computer screen (McLeod et al., 1982). A randomly generated number indicated which of the nine patterns should be emulated on a keypad by the participant on a particular trial. Participants were required to emulate as many patterns as possible by entering the patterns associated with randomly generated numbers showing up on the bottom of the screen. The divided attention task consisted of concurrent pursuit-tracking and vigilance components (Miller et al., 1988). Participants tracked a moving stimulus on the video screen using the mouse and also signaled when a small black square was displayed at any of the four corners of the video screen. The distance between the cursor and the moving stimulus was measured, as was the speed of the moving stimulus (with greater accuracy, the stimulus moved at a faster rate). During the rapid information processing task, a series of digits were displayed rapidly on the computer screen (100 digits/min), and
participants were instructed to press a key as quickly as possible after three consecutive odd or even digits (Wesnes and Warburton, 1983). During the repeated acquisition of response sequences task, four buttons were illuminated and participants were instructed to learn a 10-response sequence of button presses (Kelly et al., 1993). A position counter incremented by one each time a correct button was pressed and remained unchanged whenever the participant responded on an incorrect button. A points counter increased by one each time the 10-response sequence was correctly completed. The sequence remained the same throughout the 3-min task, but a new random sequence was generated every time the task occurred again. Participants were instructed to earn as many points as possible during the 3-min task by pressing the buttons in the correct sequence.

Physiological Measures

A blood pressure cuff was attached to the nondominant arm, and blood pressure was recorded automatically every 5 min. Participants were also connected to a pulse oximeter via a soft sensor on a finger of the nondominant hand, which continuously monitored %SpO2. For safety, supplemental oxygen (2 l/min) was provided via a nasal cannula during all experimental sessions. If oxygen saturation decreased below 90%, breaths were prompted verbally by staff, and the oxygen flow rate was increased. Average arterial oxygen saturation remained above 90% during all sessions. A specially modified Polaroid camera with a close-up lens (2× magnification) was used to take pupil photographs. All photographs were taken under ambient lighting conditions. Horizontal and vertical measurements of pupil diameter were made using calipers, and then these two measurements were averaged and divided by two to correct for the 2× magnification.

Drugs

Buprenorphine HCl for injection (4 mg/ml) was provided by the National Institute on Drug Abuse. Methadone HCl for injection (10 mg/ml) was obtained from Roxane Laboratories, Inc. (Columbus, OH). Naloxone HCl (1 mg/ml; Narcan) for injection was obtained from DuPont (Wilmington, DE). Buprenorphine and methadone were diluted in 5% dextrose to produce each dose. Placebo (5% dextrose) or active drug was administered intravenously through a catheter over a 50-s period in a total volume of 4 ml. Physiological saline solution was infused continuously during experimental sessions, except during drug administration. Between 1 and 2 ml of harneparinized saline (10 units/ml) was flushed into the catheter four to eight times each day. All venous catheters were maintained as heparin locks and were removed within 36 h of insertion. Supplemental medications available to all participants for the duration of the study included calcium carbonate (Mylanta); acetaminophen, ibuprofen, and docusate sodium (Colace); magnesium hydroxide (Milk of Magnesia); and multivitamins with iron. Trazodone HCl (Desyrel, 50 mg p.o. at bedtime; Warner Chilcott, Morris Plains, NJ) was available if participants reported having trouble sleeping. Three participants used acetaminophen during the study (mean two occasions; range one to four occasions), three used ibuprofen (mean 31 occasions; range 19–51 occasions), and one used calcium carbonate on one occasion. All six participants used trazodone during the study (mean 35 occasions; range 4–60 occasions). All six participants also used multivitamins (mean 53 occasions; range 33–66 occasions).

Morning urine samples were collected daily, and one random sample per week was screened for the presence of other illicit substances. No illicit substances, other than opioids, were found in the urine of participants.

Statistical Analyses

Repeated measures analyses of variance with planned comparisons was performed to answer the following primary questions: 1) Do buprenorphine and methadone function as reinforcers, and 2) how do the reinforcing effects of buprenorphine compare with those of methadone? Specifically, to evaluate the reinforcing effects of buprenorphine and methadone, the progressive ratio break point values and amount of drug self-administered in milligrams for each active dose were compared with placebo. To evaluate dose-related effects, the break point values for each active dose were compared with other active doses (e.g., 0.5 versus 2 mg of buprenorphine, 0.5 versus 8 mg of buprenorphine, and 2 versus 8 mg of buprenorphine). To determine whether the effects of buprenorphine differed from those produced by methadone, the following comparisons were made: 0.5 mg of buprenorphine versus 5 mg of methadone, 2 mg of buprenorphine versus 10 mg of methadone, and 8 mg of buprenorphine versus 20 mg of methadone. To assess changes in reinforcing effects across days, break point values and milligrams of drug self-administered across the two choice sessions were compared. To assess both peak and time course of effects produced by the sample dose, the subjective, physiological, and performance effects produced by each active dose were compared with those of placebo.

Drug and money break point values and milligrams self-administered were analyzed as a function of dose (0 mg, 0.5 mg of buprenorphine, 2 mg of buprenorphine, 8 mg of buprenorphine, 5 mg of methadone, 10 mg of methadone, and 20 mg of methadone) and choice session (one or two). Pupil diameter, task performance, and subjective ratings during the sample session were analyzed as a function of dose and time. SOWS data during the detoxification week were also analyzed using repeated measures analyses of variance. Only those comparisons with P values less than 0.05 were considered statistically significant. Because only one woman completed the study, it was not possible to examine potential sex differences in the present study.

ED50 values and 95% confidence limits for buprenorphine and methadone were calculated by log linear regression analysis and analyses of variance. ED50 values were defined as the doses required to produce a progressive ratio break point value of 2000 for the self-administration task; a 50-mm rating (good, high, liked, quality, or potent) or a $10 rating (pay) for the visual analog scale; a value of 2.0 for the drug effects questionnaire; 18,000 pixels for tracking distance; 6.5 pixels/s for maximum speed; and 1.5 for false alarms. Slopes of the dose-response curves were compared using parallel line assays (Finney, 1964). For each of the effects analyzed, the slopes of the buprenorphine and methadone dose-response curves were similar. Therefore, a potency ratio and 95% confidence limits could be determined using parallel line assays. A potency ratio is considered different if the 95% confidence limit does not include the value 1.0. The ED50 values, potency ratios, and 95% confidence limits were determined using the statistical software for pharmacology PharmTools Pro version 1.1.27 (PharmTools Pro, Philadelphia, PA).

Results

Self-Administration. Figure 1 shows progressive ratio break point values for drug (left) and money (middle) as a function of dose for buprenorphine and methadone. Mean drug break point values for each active dose were significantly greater than for placebo (P < 0.001 for each comparison: 0 versus 0.5 mg of buprenorphine [F1,16 = 16.8]; 0 versus 2 mg of buprenorphine [F1,16 = 22.1]; 0 versus 8 mg of buprenorphine [F1,16 = 22.1]; 0 versus 5 mg of methadone [F1,6 = 16.8]; 0 versus 10 mg of methadone [F1,6 = 21.3]; and 0 versus 20 mg of methadone [F1,6 = 30.9]). However, drug break point values did not significantly differ during the active doses, either within or between drug conditions. Drug break point values were not significantly different during the first and second choice sessions.

Mean break point values for money (Fig. 1, middle) when...
The amount of drug self-administered during choice sessions is also shown in Fig. 1 (right). As expected, based on the progressive ratio break point values, participants self-administered near maximal levels of the amount of drug available. Participants self-administered significantly more drug when 8 mg of buprenorphine was available, compared with placebo (\(F_{1,6} = 61.9\); \(P < 0.0001\)) and compared with 0.5 mg (\(F_{1,6} = 55.7\); \(P < 0.0001\)) and 2 mg of buprenorphine (\(F_{1,6} = 38.2\); \(P < 0.0001\)). Similarly, participants self-administered significantly more drug when 5 mg (\(F_{1,6} = 15.9\); \(P < 0.0004\)), 10 mg (\(F_{1,6} = 79.3\); \(P < 0.0001\)), or 20 mg (\(F_{1,6} = 394.2\); \(P < 0.0001\)) of methadone was available compared with placebo. The amount of drug self-administered when 20 mg of methadone was available was significantly greater than when 5 mg (\(F_{1,6} = 251.7\); \(P < 0.0001\)) or 10 mg (\(F_{1,6} = 119.9\); \(P < 0.0001\)) of methadone was available. Significantly more drug was also self-administered when 10 mg of methadone was available compared with 5 mg of methadone (\(F_{1,6} = 24.2\); \(P < 0.0001\)).

Subjective Effects. In contrast to the lack of a dose-response relationship for the reinforcing effects of buprenorphine and methadone, most of the subjective-effects ratings were more clearly dose-related. Figure 2 shows mean peak responses on visual analog scale ratings of “good drug effect”, “high”, and “drug liking” (Fig. 2, top). For ratings of good drug effect, all of the active doses of buprenorphine were significantly different from placebo (0 versus 0.5 mg of buprenorphine \(F_{1,6} = 6.4\), \(P < 0.02\); 0 versus 2 mg of buprenorphine \(F_{1,6} = 9.0\), \(P < 0.005\); and 0 versus 8 mg of buprenorphine \(F_{1,6} = 20.4\), \(P < 0.0001\)), and there were no statistically significant differences between the doses, although the difference between 0.5 and 8 mg of buprenorphine neared statistical significance (\(F_{1,6} = 3.9\); \(P < 0.06\)). A similar pattern was obtained for ratings of high (0 versus 0.5 mg of buprenorphine \(F_{1,6} = 6.1\), \(P < 0.02\); 0 versus 2 mg of buprenorphine \(F_{1,6} = 12.8\), \(P < 0.001\); and 0 versus 8 mg of buprenorphine \(F_{1,6} = 29.1\), \(P < 0.0001\)), with the exception that the 8-mg dose of buprenorphine was significantly different from the 0.5-mg dose (\(F_{1,6} = 8.5\); \(P < 0.007\)). For ratings of drug liking, the 8-mg buprenorphine dose was significantly different from both the 0.5-mg (\(F_{1,6} = 9.0\); \(P < 0.005\)) and 2-mg doses (\(F_{1,6} = 6.3\); \(P < 0.02\)). Similarly, ratings of drug quality (0 versus 2 mg of buprenorphine \(F_{1,6} = 4.5\), \(P < 0.04\); 0 versus 8 mg of buprenorphine \(F_{1,6} = 21.2\), \(P < 0.0001\); 0.5 versus 8 mg of buprenorphine \(F_{1,6} = 7.5\), \(P < 0.01\); and 2 versus 8 mg of buprenorphine \(F_{1,6} = 6.2\), \(P < 0.02\)), potency (0 versus 2 mg of buprenorphine \(F_{1,6} = 4.1\), \(P < 0.05\); 0 versus 8 mg of buprenorphine \(F_{1,6} = 28.8\), \(P < 0.0001\); 0.5 versus 8 mg of buprenorphine \(F_{1,6} = 9.7\), \(P < 0.004\); and 2 versus 8 mg of buprenorphine \(F_{1,6} = 8.1\), \(P < 0.008\)), and the amount of money participants were willing to pay for buprenorphine (0 versus 0.5 mg of buprenorphine \(F_{1,6} = 5.6\), \(P < 0.02\); 0 versus 2 mg of buprenorphine \(F_{1,6} = 11.4\), \(P < 0.002\); 0 versus 8 mg of buprenorphine \(F_{1,6} = 24.3\), \(P < 0.0001\); and 0.5 versus 8 mg of buprenorphine \(F_{1,6} = 6.5\), \(P < 0.02\)) were clearly dose-related (Fig. 2, middle).

For methadone, ratings of good drug effect (0 versus 10 mg of methadone \(F_{1,6} = 7.2\), \(P < 0.01\); 0 versus 20 mg of methadone \(F_{1,6} = 31.6\), \(P < 0.0001\); 5 versus 20 mg of methadone \(F_{1,6} = 16.8\), \(P < 0.0003\); and 10 versus 20 mg of methadone \(F_{1,6} = 8.6\), \(P < 0.006\), high (0 versus 10 mg of methadone \(F_{1,6} = 8.7\), \(P < 0.006\); 0 versus 20 mg of methadone \(F_{1,6} = 42.2\), \(P < 0.0001\); 5 versus 20 mg of methadone \(F_{1,6} = 25.6\), \(P < 0.0001\); and 10 versus 20 mg of methadone \(F_{1,6} = 12.6\), \(P < 0.001\)), drug liking (0 versus 10 mg of methadone \(F_{1,6} = 7.4\), \(P < 0.01\); 0 versus 20 mg of methadone \(F_{1,6} = 32.5\), \(P < 0.0001\); 5 versus 20 mg of methadone \(F_{1,6} = 17.2\), \(P < 0.0003\); and 10 versus 20 mg of methadone \(F_{1,6} = 8.9\), \(P < 0.006\)), quality (0 versus 10 mg of methadone \(F_{1,6} = 5.6\), \(P < 0.02\); 0 versus 20 mg of methadone \(F_{1,6} = 27.0\), \(P < 0.0001\); 5 versus 20 mg of methadone \(F_{1,6} = 14.1\), \(P < 0.0008\); and 10 versus 20 mg of methadone \(F_{1,6} = 7.9\), \(P < 0.008\)), potency (0 versus 10 mg of methadone \(F_{1,6} = 5.7\), \(P < 0.02\); 0 versus 20 mg of methadone \(F_{1,6} = 26.0\), \(P < 0.0001\); 5 versus 20 mg of
methadone \(F(1,6) = 13.0\), \(P < 0.001\); and 10 versus 20 mg of methadone \(F(1,6) = 7.3\), \(P < 0.01\), and the amount of money participants were willing to pay for drug (0 versus 20 mg of methadone \(F(1,6) = 21.9\), \(P < 0.0001\); 5 versus 20 mg of methadone \(F(1,6) = 10.1\), \(P < 0.003\); and 10 versus 20 mg of methadone \(F(1,6) = 8.6\), \(P < 0.006\)) were all dose-related. There were no significant differences between buprenorphine and methadone for any of the above ratings. The pattern of results obtained for ratings of “mellow” and “sedated” after administration of buprenorphine and methadone were virtually identical to good drug effect (data not shown). Ratings of “energetic” were significantly higher than placebo after administration of 10 mg \(F(1,6) = 5.4\), \(P < 0.03\) and 20 mg of methadone \(F(1,6) = 6.2\), \(P < 0.02\) but not after any of the buprenorphine doses. The durations of action of buprenorphine and methadone for all of the subjective responses were similar (i.e., 8 mg of buprenorphine was similar to 20 mg of methadone; data not shown).

In addition to positive subjective responses, 8 mg of buprenorphine also produced small, but statistically significant, increases in ratings of “bad drug effect” (0 versus 8 mg of buprenorphine \(F(1,6) = 8.3\), \(P < 0.007\) and “sleepy” \(F(1,6) = 7.0\), \(P < 0.01\); Fig. 2, bottom). Peak ratings of bad drug effect were significantly higher after 8 mg of buprenorphine compared with 20 mg to methadone \(F(1,6) = 8.3\), \(P < 0.007\). Ratings of “nauseated” were also significantly higher after 8

---

**Fig. 2.** Selected visual analog scale ratings as a function of dose and drug. Data points represent mean peak ratings for the six participants across the sample and subsequent no drug sessions. Error bars represent ± 1 S.E.M. Other details are as presented in Fig. 1.
mg of buprenorphine compared with 20 mg of methadone ($F_{(1,6)} = 5.1$); $P < 0.03$.

Drug effect questionnaire ratings of “good effects” (0 versus 0.5 mg of buprenorphine [$F_{(1,6)} = 5.9$], $P < 0.02$; 0 versus 2 mg of buprenorphine [$F_{(1,6)} = 23.6$], $P < 0.0001$; 0 versus 8 mg of buprenorphine [$F_{(1,6)} = 26.6$], $P < 0.0001$; 0.5 versus 2 mg of buprenorphine [$F_{(1,6)} = 5.9$], $P < 0.02$; 0 versus 5 mg of buprenorphine [$F_{(1,6)} = 7.5$], $P < 0.01$; 0 versus 5 mg of methadone [$F_{(1,6)} = 5.9$], $P < 0.02$; 0 versus 10 mg of methadone [$F_{(1,6)} = 15.6$], $P < 0.0004$; 0 versus 20 mg of methadone [$F_{(1,6)} = 33.3$], $P < 0.0001$; and 5 versus 20 mg of methadone [$F_{(1,6)} = 11.1$], $P < 0.002$), drug liking (0 versus 0.5 mg of buprenorphine [$F_{(1,6)} = 8.8$], $P < 0.006$; 0 versus 2 mg of buprenorphine [$F_{(1,6)} = 21.0$], $P < 0.0001$; 0 versus 8 mg of buprenorphine [$F_{(1,6)} = 4.2$], $P < 0.05$; 0 versus 5 mg of methadone [$F_{(1,6)} = 6.2$], $P < 0.02$; 0 versus 8 mg of buprenorphine [$F_{(1,6)} = 7.6$], $P < 0.01$; 0 versus 5 mg of methadone [$F_{(1,6)} = 6.2$], $P < 0.02$; 0 versus 10 mg methadone [$F_{(1,6)} = 12.8$], $P < 0.001$; 0 versus 20 mg of methadone [$F_{(1,6)} = 30.4$], $P < 0.0001$; and 5 versus 20 mg of methadone [$F_{(1,6)} = 9.2$], $P < 0.005$), and strength of drug effects (0 mg versus 0.5 mg buprenorphine [$F_{(1,6)} = 15.5$], $P < 0.0005$; 0 versus 2 mg of buprenorphine [$F_{(1,6)} = 26.2$], $P < 0.0001$; 0 versus 8 mg of buprenorphine [$F_{(1,6)} = 44.8$], $P < 0.0001$; 0.5 versus 8 mg of buprenorphine [$F_{(1,6)} = 7.6$], $P < 0.01$; 0 versus 5 mg of methadone [$F_{(1,6)} = 15.5$], $P < 0.0005$; 0 versus 10 mg of methadone [$F_{(1,6)} = 22.3$], $P < 0.0001$; 0 versus 20 mg of methadone [$F_{(1,6)} = 50.2$], $P < 0.0001$; 5 versus 20 mg of methadone [$F_{(1,6)} = 9.7$], $P < 0.004$; and 10 versus 20 mg of methadone [$F_{(1,6)} = 5.6$], $P < 0.02$) were increased in a dose-related manner for both buprenorphine and methadone, with no significant differences between the two drugs (Fig. 3). Ratings were near maximal for all of these effects at the highest doses of buprenorphine and methadone tested. Ratings of bad drug effect were not significantly increased for either buprenorphine or methadone. For methadone, one of the six participants thought that 5 and 10 mg of methadone were stimulants, and the other five participants thought that these doses were sedatives (Fig. 3, bottom right). All of the participants thought that 20 mg of methadone was a sedative. For buprenorphine, three of the participants thought that 0.5 mg of buprenorphine was placebo, and three thought that it was a sedative. One of the participants thought that 2 mg of buprenorphine was placebo, and five thought that it was a sedative. All of the participants thought that 8 mg of buprenorphine was a sedative.

Sum scores on the opioid symptom checklist increased in a dose-related manner after administration of buprenorphine and methadone. Peak ratings after the high doses of each drug were approximately 5 (range 0–12). Both 2 and 8 mg of buprenorphine were significantly different from placebo, as was 20 mg of methadone (0 versus 2 mg of buprenorphine [$F_{(1,6)} = 8.3$], $P < 0.007$; 0 versus 8 mg of buprenorphine [$F_{(1,6)} = 16.0$], $P < 0.0004$; and 0 versus 20 mg of methadone [$F_{(1,6)} = 17.8$], $P < 0.0002$). Both 2 and 8 mg of buprenorphine were also significantly different from 0.5 mg of buprenorphine (0.5 versus 2 mg of buprenorphine [$F_{(1,6)} = 4.9$], $P < 0.03$; and 0.5 versus 8 mg of buprenorphine [$F_{(1,6)} = 11.1$], $P < 0.002$). The 20-mg methadone dose was significantly different from the 5- and 10-mg doses (5 versus 20 mg of methadone [$F_{(1,6)} = 12.6$], $P < 0.001$; 10 versus 20 mg of methadone [$F_{(1,6)} = 6.0$], $P < 0.02$). There were no significant differences between buprenorphine and methadone.

Average subjective opioid withdrawal scores during the last 5 days of detoxification ranged between 16 and 21 (scores could range from 0–64). Average peak SOWS scores during experimental sessions ranged between 7 and 11 and were not related to dose.

**Performance Effects.** Buprenorphine had few effects on performance, with the exception of small impairments in performance of the divided attention task. Relative to placebo, both 2 and 8 mg of buprenorphine significantly increased the mean peak latency to respond correctly to a random distracter stimulus on the computer screen (0 versus 2 mg of buprenorphine [$F_{(1,6)} = 4.4$], $P < 0.04$; and 0 versus 8 mg of buprenorphine [$F_{(1,6)} = 8.1$], $P < 0.008$). There were no statistically significant changes in latency to respond correctly to the stimulus after methadone administration, although there were trends for 20 mg of methadone to impair performance on this task (0 versus 20 mg of methadone [$F_{(1,6)} = 3.3$]; $P < 0.08$). Across the two drugs tested, 2 mg of buprenorphine produced significantly longer latencies to respond than 10 mg of methadone ($F_{(1,6)} = 5.0$); $P < 0.03$). The effects of methadone on task performance were not significantly different from placebo.

Secondary analysis of the data as a function of drug and time revealed further changes in performance of the divided attention task (Fig. 4). Tracking distance (distance between the cursor and the moving stimulus on the computer screen) was significantly longer after administration of 8 mg of buprenorphine compared with placebo ($F_{(1,6)} = 4.9$); $P < 0.03$; Fig. 4, left). The difference in tracking distance between 0.5 and 8 mg of buprenorphine approached statistical significance ($F_{(1,6)} = 3.6$); $P < 0.07$), as did the difference between 5 and 20 mg of methadone ($F_{(1,6)} = 3.1$); $P < 0.09$). The maximum speed reached by the moving stimulus significantly decreased after administration of 2 and 8 mg of buprenorphine but not after administration of any of the methadone doses (0 versus 2 mg of buprenorphine [$F_{(1,6)} = 9.7$], $P < 0.004$; and 0 versus 8 mg of buprenorphine [$F_{(1,6)} = 8.7$], $P < 0.006$; Fig. 4, middle). Finally, the number of false alarms (responses made when the distracter stimulus did not actually come into view) significantly increased after administration of 8 mg of buprenorphine, relative to placebo ($F_{(1,6)} = 4.4$); $P < 0.04$; Fig. 4, right).

**Physiological Effects.** Compared with placebo, all of the active buprenorphine doses produced significant decreases in pupil diameter (0 versus 0.5 mg of buprenorphine [$F_{(1,6)} = 4.1$], $P < 0.05$; 0 versus 2 mg of buprenorphine [$F_{(1,6)} = 16.6$], $P < 0.0003$; 0 versus 8 mg of buprenorphine [$F_{(1,6)} = 20.4$], $P < 0.0001$). The myotic effects produced by both 2 and 8 mg of buprenorphine were significantly different from 0.5 mg of buprenorphine (0.5 versus 2 mg of buprenorphine [$F_{(1,6)} = 4.2$], $P < 0.05$; 0.5 versus 8 mg of buprenorphine [$F_{(1,6)} = 6.3$], $P < 0.02$), but there were no differences between 2 and 8 mg
of buprenorphine. The 20-mg dose of methadone produced miotic effects that were significantly different from those of placebo $F(1,6) = 7.1; P < 0.01$, 5 mg $F(1,6) = 12.0; P < 0.002$, and 10 mg $F(1,6) = 5.6; P < 0.02$. Comparing across drugs, significant differences were obtained for the miotic effects produced by 0.5 mg of buprenorphine compared with 5 mg of methadone $F(1,6) = 7.9; P < 0.008$ and 2 mg of buprenorphine compared with 10 mg of methadone $F(1,6) = 14.4; P < 0.0007$. However, there were no significant differences between 8 mg of buprenorphine and 20 mg of methadone.

Average arterial oxygen saturation was reduced in a dose-related manner by 2 mg $F(1,6) = 5.7; P < 0.02; 96.2\%$ and 8 mg $F(1,6) = 8.3; P < 0.007; 96.0\%$ buprenorphine, relative to placebo (97.0%). The effects of 0.5 mg of buprenorphine (97.0%) were also significantly different from 2 mg $F(1,6) = 6.0; P < 0.02$ and 8 mg of buprenorphine $F(1,6) = 8.6; P < 0.006$. The maximal decreases in arterial oxygen saturation occurred within 30 to 60 min after administration of 8 mg of buprenorphine. Although methadone also produced slight decreases in arterial oxygen saturation, these changes were not statistically significant. Please note that arterial oxygen saturation was measured in the presence of supplemental oxygen, so the small reductions seen here were not entirely surprising.

For the cardiovascular measures, there were no significant changes in heart rate as a function of dose, although the main effect of time was significant $F(1,18) = 13.7; P < 0.0001$, with heart rate steadily decreasing throughout the session. Sys-

![Fig. 3. Drug effects questionnaire ratings as a function of dose and drug. Data points represent mean peak ratings for the six participants across the sample and subsequent no drug sessions. Error bars represent ± 1 S.E.M. Other details are as presented in Fig. 1.](https://pet.aspetjournals.org/doi/fig/10.1124/jpet.1327.013277)
Dysrmonic pressure significantly increased after administration of 
2 mg of buprenorphine \[ F(1,6) = 5.3; P < 0.03; \text{mean } 116 \text{ mm Hg}\], 8 mg of buprenorphine \[ F(1,6) = 8.7; P < 0.006; \text{mean } 118 \text{ mm Hg}\], and 20 mg of methadone \[ F(1,6) = 4.1; P < 0.05; \text{mean } 115 \text{ mm Hg}\], relative to placebo (mean 109 mm Hg). However, these changes were not clinically significant. Diastolic pressure did not significantly increase for any of the active doses, relative to placebo.

**Potency Estimates.** ED\(_{50}\) values and 95% confidence limits were determined for the reinforcing, subjective, and physiological effects of buprenorphine and methadone (Table 1). Potencies for buprenorphine and methadone to produce self-administration, subjective effects, and physiological effects ranged from 0.27 to 8.6 mg (32-fold range) and from 6.1 to 20 mg (3.2-fold range), respectively. Buprenorphine was significantly more potent than methadone for all behavioral and physiological effects, with the exception of “potent” ratings on the visual analog scale and false alarms. For potent ratings on the visual analog scale and false alarms, buprenorphine was 4.6 and 5.8 times more potent than methadone, respectively, but the confidence limits were large and included 1. In general, the potency ratios for buprenorphine relative to methadone were similar in the self-administration task (5.0-fold) and for subjective effects on the DEQ (4.4–5.5-fold) as well as “quality” and potent on the visual analog scale (4.5–4.6-fold). However, potency ratios between buprenorphine and methadone were higher for most of the subjective effects on the visual analog scales (8.5–12-fold) and the physiological effects (28–51-fold).

**Discussion**

Similar to findings from our previous studies (Comer and Collins, 2002; Comer et al., 2002), the present results demonstrate that intravenously administered buprenorphine served as a reinforcer in recently detoxified, nontreatment-seeking heroin abusers. The maximum reinforcing effects of buprenorphine and methadone did not differ from each other, nor did they differ across any of the active doses tested. Drug self-administration occurred at some doses (e.g., 5 mg of methadone), despite the presence of only minimal subjective responses. Similar results were obtained in our previous study after administration of the buprenorphine/naloxone combination (Comer and Collins, 2002). Other studies have also shown that subjective effects do not necessarily predict self-administration behavior (Lamb et al., 1991; Comer et al., 1997, 1998; Heishman et al., 2000). One potential variable that may have contributed to the pattern of self-administra-

![Fig. 4. Performance on the divided attention task as a function of dose and drug. Data points represent mean scores across time for the six participants during the sample session and subsequent no-drug sessions. Tracking distance is the distance between the cursor and a moving stimulus on the computer screen (left), maximum speed is the highest speed with which the stimulus moves across the computer screen (the speed increases as the accuracy in tracking the moving stimulus increases; middle), and false alarms are the number of responses made when a distracter stimulus is not actually present (right). Error bars represent ± 1 S.E.M. Other details are as presented in Fig. 1.](image-url)
tion in the current study was the presence of mild, residual withdrawal symptoms during testing. As noted above, subjective ratings of withdrawal were still slightly elevated during testing. Some participants reported during a debriefing session after study completion that they sometimes self-administered the drug, although they did not experience any subjective effects because they noticed that they slept better that night. It is possible that the drugs were serving as both positive and negative reinforcers under the present experimental conditions (i.e., for their euphoric effects and to alleviate withdrawal). An additional complication for comparing subjective responses and self-administration may be efficacy requirement across different subjective effect measures. For example, in the present study, the potency differences between buprenorphine and methadone were generally greater on the visual analog scales than the DEQ, which may reflect the quantal nature of the DEQ compared with the continuous measure of subjective responses obtained from the visual analog scales. As in previous studies, the present results demonstrate that subjective responses and drug-taking behavior are not always directly correlated. Alternatively, the subjective responses and drug-taking behavioral measures may require different degrees of relative efficacy for agonists to produce maximum or near-maximum effects as reflected in the potency ratio differences for buprenorphine and methadone in the present study.

Results from the present study are consistent with previous research conducted in nonhuman primates demonstrating that buprenorphine serves as a reinforcer, and they provide additional evidence that the reinforcing effects of buprenorphine do not significantly differ from those of methadone. It is important to emphasize, however, that the present study was conducted in recently detoxified individuals. Previous studies conducted in laboratory animals have demonstrated that the reinforcing effects of buprenorphine are reduced to a greater extent than those of other μ opioid agonists in animals treated chronically with morphine. For example, under control conditions, alfentanil, heroin, morphine, buprenorphine, and nalbuphine all served as reinforcers (the rates of responding for these drugs were significantly greater than for placebo; Winger and Woods, 2001). However, when the animals were treated chronically with morphine, the potency of alfentanil was unchanged and the potencies of heroin and morphine were reduced only slightly. In contrast, both the potency and reinforcing effectiveness of buprenorphine and nalbuphine were reduced substantially in monkeys treated chronically with morphine. Similar results have been obtained for the analgesic and discriminative stimulus effects of buprenorphine relative to other μ opioid agonists (Young et al., 1991; Paronis and Holtzman, 1992; Pitts et al., 1998; Walker et al., 1998; Barrett et al., 2001; Walker and Young, 2001, 2002). The data collected in laboratory animals were consistent with those collected in human research volunteers. Hydromorphone produced robust subjective and physiological responses in methadone-maintained volunteers, whereas the effects of a wide range of buprenorphine doses were reduced substantially (Strain et al., 1992, 1995). Under some conditions, buprenorphine precipitated withdrawal symptoms in methadone-maintained participants (Strain et al., 1995; Walsh et al., 1995). Together, these results suggest that, under nondependent conditions, buprenorphine has moderate to robust reinforcing effects, but in opioid-dependent individuals, the reinforcing effects of buprenorphine may be minimal. However, in opioid-dependent individuals, we would predict that the potency ratios for buprenorphine and methadone would increase across all measures in direct relation to the degree of dependence. In other words, greater opioid dependence will be associated with a greater reduction in potency for buprenorphine compared with methadone.

The pattern of subjective responses after intravenous administration of buprenorphine and methadone in the present study was similar to that reported after subcutaneous administration of buprenorphine and methadone (Jasinski et al., 1978). In the present study, higher doses of buprenorphine were tested, and there were hints of a ceiling effect on several of the subjective responses, particularly on the drug effects questionnaire. Although there were few overall differences in the subjective effects produced by buprenorphine and methadone, there was some evidence for subtle differences between the two drugs in their potency to produce different subjective effects. For example, buprenorphine produced small but statistically significant increases in ratings of bad drug effects, and ratings of nausea were significantly higher for 8 mg of buprenorphine compared with 20 mg of methadone.

The subjective effects found in the present study and those reported by Jasinski et al. (1978) differ somewhat from those reported recently by Umbricht et al. (2004), in which high doses of intravenously delivered buprenorphine (0, 2, 4, 8, 12, and 16 mg) were administered to nondependent opioid abusers. Because of high variability in subjective responses among participants in that study, there were few statistically significant differences between active drug and placebo. One effect that did show significant changes as a function of dose was “drug effect”. However, at the highest dose tested (16 mg), the majority of participants reported that the effects were “weaker” than for the other doses (Umbricht et al., 2004). Similarly, an inverted U-shaped dose-response curve for buprenorphine has been reported for other effects, such as analgesia (Cowen et al., 1977; Dum and Herz, 1981; Walker et al., 1995), and is thought to reflect its increasing antagonist effects at these higher doses. In one other study, a relatively flat dose-response curve for the subjective effects of intravenously delivered buprenorphine was found (Pickworth et al., 1993). In the present study, there was little evidence for an inverted U-shaped dose-response curve. The reason for the inverted, flat, or dose-dependent effects of buprenorphine among the published studies may be due to the different behavioral measures examined. Future experiments examining the relative efficacy requirements of the different behavioral measures may help clarify the differences among the studies for buprenorphine.

Buprenorphine produced few effects on performance, which is consistent with other studies showing either mild (Pickworth et al., 1993; Comer and Collins, 2002; Comer et al., 2002) or no performance-impairing effects (Walsh et al., 1994) in opioid-experienced individuals. In relatively opioid-naive individuals, performance of the digit-symbol substitution task as well as four other psychomotor tests was impaired in a dose-related manner after acute intravenous administration of buprenorphine (Zaeny et al., 1997). In the present study, the degree of impairment produced by intravenous buprenorphine was also dose-related, but it was rel-
ED50 values across the different measures spanned a 30-fold range, particularly at high doses given intravenously, which is the route by which buprenorphine is often administered. In conclusion, the present results confirmed our hypothesis that buprenorphine would serve as a reinforcer under these conditions. The fact that the maximum break point values did not differ between buprenorphine and methadone was consistent with several previous studies conducted in laboratory animals showing that, under some conditions, buprenorphine produces effects that are indistinguishable from those of other μ opioid agonists with high efficacy. The fact that both buprenorphine and methadone were more potent in producing reinforcing effects than in producing some subjective and physiological effects was also not entirely surprising. This finding is again consistent with studies conducted in laboratory animals showing that the potency of a particular drug can vary significantly across different conditions, and this effect is greater for lower efficacy agonists than higher efficacy agonists. For example, in the present study, the buprenorphine ED₅₀ values across the different measures spanned a 30-fold potency range, whereas methadone ED₅₀ values only spanned a 3-fold potency range. Whether the reinforcing effects of buprenorphine are suppressed to a greater extent than those of other μ opioid agonists in opioid-dependent individuals is not currently known. Future studies will examine the reinforcing effects of buprenorphine compared with a range of other μ opioid agonists in morphine-maintained individuals to examine their relative efficiencies.

Acknowledgments
