ABSTRACT

By controlling access to the brain, the blood-brain barrier (BBB) restricts the entry of proteins and potential drugs to cerebral tissues. We demonstrate here the transcytosis ability of aprotinin and peptides derived from Kunitz domains using an in vitro model of the BBB and in situ brain perfusion. Aprotinin transcytosis across bovine brain capillary endothelial cell (BBCEC) monolayers is at least 10-fold greater than that of holotransferrin. Sucrose permeability was unaffected by high concentrations of aprotinin, indicating that transcytosis of aprotinin was unrelated to changes in the BBCEC monolayer integrity. Alignment of the amino acid sequence of aprotinin with the Kunitz domains of human proteins allowed the identification and design of a family of peptides, named Angiopeps. These peptides, and in particular Angiopep-2, exhibit higher transcytosis capacity and parenchyma accumulation than aprotinin. Overall, these results suggest that these Kunitz-derived peptides could be advantageously used as a new brain delivery system for pharmacological agents that do not readily enter the brain.

Blood-brain barrier (BBB) permeability is frequently a rate-limiting factor for the penetration of proteins, pharmacological agents, or peptides into the central nervous system (CNS) (Pardridge, 1999; Bickel et al., 2001). The BBB is mainly formed by brain capillary endothelial cells that are closely sealed by tight junctions. Brain capillaries also possess few fenestrae and few endocytic vesicles, compared with the capillaries of other organs (Pardridge, 1999). There is little transit across the BBB of large, hydrophilic molecules aside from some specific proteins such as transferrin, lactoferrin, and low-density lipoproteins, which are taken up by receptor-mediated endocytosis (Fillebeen et al., 1999; Pardridge, 1999; Tsuji and Tamai, 1999). It has been estimated and reported that the transport of small molecules across the BBB is the exception rather than the rule and that 98% of all small molecules do not cross the BBB (Pardridge, 2005). Because most drugs do not cross the BBB, few treatments are available against most CNS disorders, including Parkinson’s disease, Alzheimer’s disease, and brain cancers (Pardridge, 2001, 2005). Several approaches have been described for drug delivery to the brain, such as local invasive delivery by direct injection or infusion, induction of enhanced permeability, and various physiological targeting strategies (Begley, 2004; Gaillard et al., 2005; Pardridge, 2006).

Different transporters and receptors present at the BBB have been described as playing roles in maintaining the integrity of the BBB and brain homeostasis. Among them, the low-density lipoprotein receptor-related protein (LRP) has been reported to possess the ability to mediate transport of ligands across endothelial cells of the BBB (Shibata et al., 2000; Ito et al., 2006; Bell et al., 2007). For example, the passage of two members of the transferrin family, lactotransferrin and melanotransferrin, involves LRP (Fillebeen et al., 1999; Demeule et al., 2002). It has also been proposed that the receptor-associated protein (RAP) can be efficiently transferred from the blood to the brain by LRP-mediated transcytosis (Pan et al., 2004). LRP has also been suggested to mediate the brain uptake of the tissue type plasminogen activator (Benchenane et al., 2005). Both LRP and megalin (LRP2) have been shown to be responsible for the endocytosis of secreted β-amyloid precursor protein (APP) (Kounnas et al., 1995; Cam and Bu, 2006). Interestingly, it has been

ABBREVIATIONS: BBB, blood-brain barrier; CNS, central nervous system; LRP, low-density lipoprotein receptor-related protein; RAP, receptor-associated protein; APP, amyloid precursor protein; KPI, Kunitz protease inhibitor; BBCEC, bovine brain capillary endothelial cell; BSA, bovine serum albumin; PBS, phosphate-buffered saline; HPLC, high-performance liquid chromatography; TCA, trichloroacetic acid; LDL, low-density lipoprotein; Vd, volume of distribution.
demonstrated that APP lacking the Kunitz protease inhibitor (KPI) domain is a poor substrate for LRP, suggesting that this domain is important for the recognition, internalization, and clearance of APP by LRP (Kounnas et al., 1995).

Aprotinin, a 6500-Da protease inhibitor is a LRP and LRP2 ligand, and also possesses a KPI domain (Moostrup et al., 1995; Hussain et al., 1999). In the present study, we investigated whether aprotinin crosses the BBB. To verify this hypothesis, we evaluated the transcytosis of aprotinin using both a well established in vitro model of the BBB (Dehouck et al., 1992; Fillebeen et al., 1999) and in situ brain perfusion in mice (Dagenais et al., 2000). The in vitro model consists of a coculture of bovine brain capillary endothelial cells (BBCEC) and rat glial cells. It presents ultrastructural features characteristic of brain endothelium, including tight junctions, lack of fenestration, lack of transendothelial channels, low permeability for hydrophilic molecules, and a high electrical resistance (Dehouck et al., 1992). The results obtained within vitro and in vivo models provided evidence for greater passage of aprotinin across the BBB than of holo-transferrin.

We identified a family of peptides, named Angiopeps, that were derived from the Kunitz domain and that demonstrated higher transcytosis capacity than did aprotinin. Overall, these are the first results indicating that Angiopeps could be used as a peptide-based delivery technology that provides a noninvasive and flexible platform for transporting drugs or biologically active molecules into the central nervous system.

Materials and Methods

Materials

Aprotinin, bovine serum albumin (BSA), lactoferrin, holo-transferrin, human antibodies (IgG), and iodo-beads were purchased from Sigma-Aldrich (Oakville, ON, Canada) whereas RAP was from Oxford Biomedical Research (Oxford, MI). Peptides (Angiopep-1, -2, -5, and -7) were synthesized by Peptisyntha (Torrance, CA). Bovine brain endothelial cells, rat astrocytes, and serum for the in vitro BBB models were purchased from Cellial Technologies ( Lens, France). Other biochemical reagents were purchased from Sigma-Aldrich.

Iodination of Proteins

Proteins (aprotinin, transferrin, human IgG, RAP, and BSA) and peptides were radiolabeled with standard procedures using an iodo-beads kit and D-Sult dextran desalting columns from Pierce Chemical (Rockford, IL). A ratio of two iodo-beads per aprotinin was used for the labeling. In brief, beads were washed twice with 3 ml of PBS on a Whatman filter and resuspended in 60 μl of PBS. Na125I (1 mCi) from GE Healthcare (Baie d’Urfe, QC, Canada) was added to the bead suspension for 5 min at room temperature. Iodination of each protein was initiated by the addition of 100 μg of protein (80–100 μl) diluted in 0.1 M phosphate buffer solution, pH 6.5. After incubation for 10 min at room temperature, iodo-beads were removed, and the supernatants were applied onto a desalting column prepacked with 5 ml of cross-linked dextran from Pierce Chemical. 125I-proteins were eluted with 10 ml of PBS (150 mM NaCl, 2.7 mM KCl, 1.3 mM KH2PO4, and 8.1 mM Na2HPO4; pH 7.4). Kunitz-derived peptides were radioiodinated using the same procedures as for aprotinin. After the screening of the peptides, Angiopep-1, -2, -5, and -7 were radiolabeled using iodo-beads and the same procedures. 125I-Angiopeps were purified by hydrophobic chromatography using 30 RPC resin (GE Healthcare) to remove free iodine. Purified radiolabeled peptides were then analyzed by HPLC and C18 column.

In Vitro Transcytosis Studies

Preparation of Astrocytes. Primary cultures of mixed astrocytes were prepared from cerebral cortices of newborn rats (Dehouck et al., 1992). In brief, after removing the meninges, the brain tissue was gently forced through an 82-μm nylon sieve. Astrocytes were then washed twice with 3 ml of PBS containing a concentration of 1.2 × 106 cells/ml in 2 ml of optimal culture medium (Dubelcco’s modified Eagle’s medium) supplemented with 10% heat-inactivated fetal calf serum, 2 mM glutamine, and 50 μg/ml gentamycin. The medium was changed twice a week. BBCECs were cultured in the presence of Dubelcco’s modified Eagle’s medium supplemented with heat-inactivated 10% (v/v) horse and 10% calf sera, 2 mM glutamine, 50 μg/ml gentamycin, and 1 ng/ml basic fibroblast growth factor, added every other day.

Blood-Brain Barrier Model. The in vitro model of BBB was established by using a coculture of BBCECs obtained from Cellial Technologies and newborn rat astrocytes as described previously (Dehouck et al., 1992). In brief, before cell coculture, plate inserts (Millicell-PC 3.0 μM, 30 mm in diameter; Millipore Corporation, Billerica, MA) were coated on the upper surface with rat tail collagen. They were then set in the six-multiwell microplates containing astrocytes prepared as described above, and BBCECs were plated on the upper side of the filters in 2 ml of culture medium. BBCEC medium was changed three times a week. Under these conditions, differentiated BBCECs formed a confluent monolayer after 7 days. Experiments were performed between 5 and 7 days after coculture was reached. The number of cells at confluence was 400,000 cells/4.2 cm2 or 90 μg of protein/4.2 cm2, as evaluated by a micro-bichoronic acid assay from Pierce Chemical. For the screening of the 96 peptides, 1.1-cm2 filters were used.

Transcytosis Experiments. Transcytosis experiments were performed as follows. Filters were washed with Ringer/HEPES solution, and 125I-protein or 125I-peptide (10–250 nM) was then added to the solution bathing the upper side of the insert. Transcytosis of various 125I-proteins were tested (aprotinin, RAP, transferrin, human IgG, and BSA) using this in vitro BBB model. At various times, the insert was sequentially transferred into a fresh well to avoid possible re-endoctysis of proteins, peptides or Angiopep conjugates by the abluminal side of the BBCECs. At the end of the experiment, 125I-proteins were quantified in 500 μl of the lower chamber of each well by precipitating them with TCA. TCA precipitation was performed to the collected 500 μl followed by 500 μl of TCA 50% for a final concentration of 20%. After 10 min at 4°C, the tubes were centrifuged for 10 min at 10,000 rpm. Radioactivity in the pellet was estimated with a gamma scintillation counter. We also measured peptide in 50 μl of the lower chamber of each well by SDS-polyacrylamide gel electrophoresis. Peptides were separated on 12.5% Tricine gels, stained with Coomassie Blue.

Sucrose Permeability. The permeability coefficient for sucrose was measured to verify the integrity and tightness of the BBCEC monolayers. Brain endothelial cell monolayers grown on inserts were transferred to six-well plates containing 2 ml of Ringer/HEPES well (basolateral compartment). In each apical chamber, the culture medium was replaced by Ringer/HEPES containing 74 nM [14C]sucrose (microliters) as a function of time (minutes). The permeability coefficient (Pe) for sucrose was calculated as described previously by Dehouck et al. (1992), using filters either coated with endothelial cells or uncoated. The results were plotted as the clearance of [14C]sucrose (microliters) as a function of time (minutes). The permeability coefficient (Pe) was calculated as 1/Pe = 1/PSt −
In Situ Mouse Brain Perfusion

Transport Studies. The initial uptake of 125I-aprotinin, 125I-peptides, or [14C]ulin was measured using the in situ brain perfusion method adapted in our laboratory for the study of drug uptake in the mouse brain (Dagenais et al., 2000; Cistermino et al., 2001). In brief, the right common carotid artery of ketamine/xylazine (140/8 mg/kg i.p.)-anesthetized mice was exposed and ligated at the level of the bifurcation of the common carotid, rostral to the occipital artery. The common carotid was then catheterized rostrally with polyethylene tubing filled with 25 U/ml heparin, and it was mounted on a 20-gauge needle. The syringe containing the perfusion fluid (125I-proteins in Krebs/bicarbonate buffer at pH 7.4, gassed with 95% O2 and 5% CO2) was placed in an infusion pump (pump PHD 2000; Harvard Apparatus Inc., Holliston, MA) and connected to the catheter. Before the perfusion, the contralateral blood flow contribution was eliminated by severing the heart ventricles. The brain was perfused for the indicated times (2.5–15 min) at a perfusion rate of 1.15 ml/min. After perfusion of radiolabeled molecules, the brain was further perfused for 60 s with Krebs buffer, to wash away excess 125I-proteins. Mice were then decapitated to terminate perfusion, and the right hemisphere was isolated on ice before being subjected to capillary depletion. In brief, for capillary depletion, the mice brain homogenized on ice in Ringer-HEPES buffer with 0.1% BSA in a glass homogenizer. Brain homogenate was then mixed thoroughly with 35% dextran 70 (50/50), and it was centrifuged at 5400g for 10 min at 4°C. The supernatant composed of brain parenchyma and the pellet representing capillaries were then carefully separated. Aliquots of homogenates, supernatants, pellets, and perfusates were taken to measure their contents of 125I-proteins by TCA precipitation and to evaluate the apparent volume of distribution (Vd).

Data Analysis

Data are expressed as mean ± S.D. Statistical analyses were performed using Student’s t test when one group was compared with the control group. To compare two or more groups with the control group, one-way analysis of variance with Dunnett’s post hoc test was used. In addition, curves were statistically different. All statistical analyses were performed using GraphPad Prism version 4.0C for Macintosh (GraphPad Software Inc., San Diego, CA). Significance was assumed for p values less than 0.5.

Results

To evaluate and characterize the transcytosis of aprotinin, we used an in vitro model of the BBB. After iodination with BioBeads, transcytosis of 250 nM 125I-aprotinin and 125I-holo-transferrin across endothelial cell monolayers was compared using this model (Fig. 1). Transport from the apical to the basolateral side of 125I-aprotinin was much higher than for 125I-holo-transferrin. In addition, the effect of aprotinin on the BBB integrity was determined by measuring sucrose permeability in the presence or absence of a high aprotinin concentration (5 μM). The clearance of sucrose measured in the presence of aprotinin was similar to that measured for the control. Under both conditions, the sucrose permeability coefficient was equivalent, 0.45 ± 0.05 × 10−3 cm/min, indicating that aprotinin does not affect BBB integrity.

The passage of 125I-aprotinin across BBCEC was also evaluated at 4°C (Fig. 1B). Aprotinin was boiled for 15 min to evaluate the transport rate of denatured-125I-aprotinin. The transport rate of 125I-aprotinin at 4°C was strongly reduced compared with that measured at 37°C. The passage of denatured-125I-aprotinin was very similar to the transport value obtained at 4°C. These results indicate that transcytosis of 125I-aprotinin from the apical to the basolateral side in this BBB model is sensitive to temperature and to the native conformation of aprotinin, suggesting that the transcytosis of 125I-aprotinin involves a receptor.

The transport across the BBCEC monolayers of 125I-aprotinin and other proteins at the same concentration (250 nM) is compared in Table 1. Transport rates are expressed in terms of picomoles per squared centimeter per hour. These results indicate that 125I-aprotinin transport is higher than

\* Also known as Angiopep-1.
Fig. 3. Volumes of distribution of Angiopeps in the brain parenchyma measured by in situ brain perfusion. A, amino acid sequence of tested Angiopeps are presented. Changes in the amino acid sequence (when compared with Angiopep-1) are indicated in bold and with an asterisk. B, mice were perfused with 100 nM 125I-Angiopeps for 5 min as described under Materials and Methods. After perfusion, brain capillary depletion was performed on the mice right brain hemispheres. The amount of radioactivity associated with total brain homogenate, the brain capillary fraction and the parenchyma was evaluated in a gamma counter. The results were expressed as the apparent Vd for the 125I-Angiopeps found in these brain compartments. Data represent the means ± S.D. obtained for at least three mice.

Fig. 4. HPLC analysis of 125I-Angiopep-2. After the radiolabeling and purification of the labeled peptide on 30 RPC resin using AKTA explorer, HPLC analysis was performed at a flow rate of 1 ml/min to evaluate the incorporation of 125I on Angiopep-2. A, the peptide was followed at a wavelength of 229 nm. B, fractions of 1 ml were collected, and the radioactivity associated with these fractions was quantified in a gamma counter. The major peak of radioactivity was found in the fraction 7, which corresponds to the retention time of the 125I-Angiopep-2 (7 min).
uptake of this peptide (Angiopep-2), as measured by in situ brain perfusion, was similar to that of Angiopep-1 (Fig. 3B). Second, the lysine residue at position 10 was replaced by an arginine (creating Angiopep-5), whereas in Angiopep-7, the lysine at positions 10 and 15 were replaced by arginine residues. Each of these three peptides (Angiopep-2, Angiopep-5, and Angiopep-7) has a net charge of +2. However, parenchymal uptake for both Angiopep-5 and Angiopep-7 was decreased by approximately 60 and 85%, respectively. These results suggest that the replacement of the cysteine by a serine has a low impact on the parenchymal transport. In contrast, replacement of the lysine residues at positions 10 and 15 prevents the transport capacity.

An example of peptide radiolabeling is shown in Fig. 4. After the screening of the 96 peptides, the selected peptides were purified following iodination by reverse phase using 30RPC resin and AKTA explorer system to remove excess of free $^{[125I]}$ iodine. Then, radiolabeled peptides were analyzed by HPLC on a C18 column at 229-nm wavelength. In Fig. 4A, a chromatogram of $^{125I}$-Angiopep is presented. Fractions were collected and measured for radioactivity. As shown in Fig. 4B, the peak of radioactivity corresponds to the UV peak of Angiopep-2 detected in Fig. 4A. In this case, more than 92% of the radioactivity was found in this peak, and the specific activity estimated for $^{125I}$-Angiopep-2 was 340,000 cpm/µg or 0.44 Ci/nmol.

We further characterized the transport of aprotinin and Angiopep-2 using the in vitro BBB model. As shown in Fig. 5A, Angiopep-2 transcytosis was also found to be 7-fold higher than that of aprotinin, confirming the results obtained by in situ brain perfusion. Transport from the apical to the basolateral side of $^{125I}$-Angiopep-2 was much higher than for $^{125I}$-aprotinin. Previous studies have showed that aprotinin is a ligand for receptor(s) of the LRP1 (α2-macroglobulin receptor) or LRP2 (mealin) (Moestrup et al., 1995). Here, to determine whether the transcytosis of aprotinin and Angio-

Fig. 5. Transcytosis of $^{125I}$-Angiopep-2 from the apical to the basolateral side of endothelial cell monolayers. Transport of aprotinin and Angiopep-2 (250 nM) was measured from the apical to the basolateral side of the BBCEC monolayers as described under Materials and Methods.
pept-2 could involve LRP, we measured the impact of RAP, a chaperone protein for all members of the low-density lipoprotein (LDL)-receptor family, on the aprotinin transcytosis (Fig. 5B). The addition of RAP inhibited the transport of $^{125}$I-aprotinin from the apical to the basolateral side of endothelial cell monolayers of this in vitro BBB model (Fig. 5B, left). By recuperating filters coated with BBCEC, we estimated the accumulation $^{125}$I-aprotinin in these endothelial cells (Fig. 5B, right). In the presence of RAP, the inhibition of $^{125}$I-aprotinin transcytosis also led to an increase in its accumulation in BBCECs. The transcytosis of Angiopep-2 was reduced by approximately 45% with the addition of RAP (Fig. 5C). Thus, the addition of RAP partially reduced the transcytosis of both aprotinin and Angiopep-2. This inhibition by RAP suggests that Angiopep-2 retains its capacity to interact with aprotinin receptor.

The apparent distribution volume of Angiopep-2 measured by in situ brain perfusion indicated that the brain and parenchymal volume of distribution for Angiopep-2 is much higher than for transferrin and aprotinin after 5 min perfusion (Fig. 6). Furthermore, the apparent distribution volume in brain parenchyma of Angiopep-2 increased linearly for at least 15 min of perfusion and was much higher than for the vascular marker $^{14}$C-inulin (Fig. 7A). Moreover, the addition of Angiopep-2 (up to 500 nM) did not affect the volume of distribution for inulin (Fig. 7B), indicating that the BBB integrity was unaffected under these conditions by the peptide. To demonstrate that receptor-mediated transcytosis could participate in the transport of Angiopep-2 across the BBB, in situ brain perfusion was performed in the presence of an excess of unlabeled Angiopep-2. As shown in Fig. 8A, the addition of unlabeled Angiopep-2 (0.5 and 10 μM) to the perfusate reduced the brain $V_d$ of $^{125}$I-Angiopep-2 (0.025 μM) by 50%, whereas aprotinin at 10 μM reduced it by 40% (Fig. 8B). Overall, these data suggest that a portion of the transport of Angiopep-2 at the BBB is partially saturable and that receptor-mediated transcytosis is involved.

**Fig. 6.** Effect of RAP on aprotinin and Angiopep transcytosis across BBCEC monolayers. A, transcytosis (left) across BBCEC monolayers and accumulation inside BBCECs (right) of $^{125}$I-aprotinin were measured for 1 h in the presence or absence of 50 μg/ml RAP as described under Materials and Methods. Data represent the means ± S.D. obtained from three different experiments performed in triplicate. B, transcytosis of $^{125}$I-Angiopep-2 was also evaluated in the presence of RAP. Data represent the means ± S.D. obtained from six different filters. *, $p < 0.05$, significant difference compared with control.

**Discussion**

In the development of new therapies to treat brain pathologies, the BBB is a major obstacle against the use of potential drugs for treating disorders of the CNS (Begley, 2004). In the present study, we report that peptides derived from the Kunitz domain have a higher brain penetration capability than do other proteins, such as transferrin, as shown using both an in vitro model of the BBB and in situ brain perfusion in mice. These data suggest that Angiopep could be used as a brain delivery system for macromolecules.

We first demonstrated here that aprotinin transcytosis across BBCEC monolayers is at least 8-fold higher than that of transferrin. This high transcytosis of aprotinin was not related to changes in the BBCEC monolayer integrity as measured by the sucrose permeability. The temperature and conformational dependence of the transendothelial transport of aprotinin suggest the involvement of a mechanism implicating receptor-mediated transcytosis. Previous studies using technetium-99m-labeled aprotinin, which requires partial reduction of the protein disulfide bonds and the chelation of the generated sulphydryl groups, have reported low brain accumulation compared with other tissues (kidney and liver) (Schaadt et al., 2003; Sojan et al., 2005). Here, transcytosis using both an in vitro BBB model and in situ brain perfusion clearly showed that aprotinin crosses the BBB much more efficiently than other proteins. The brain accumulation and the high rate of aprotinin transcytosis suggested that aprotinin or an aprotinin-derived peptide could be advantageously used as a new delivery system for the brain.

To identify the minimal sequence required for transport of aprotinin across the BBB, we looked for sequence homologies with other proteins having similar properties. Several hits were obtained with the C-terminal portion, which includes the Kunitz domain of aprotinin. Alignment of proteins with the highest scores allowed us to design more than 96 human aprotinin-derived peptides. These peptides were tested using the BBB in vitro model and in situ brain perfusion. From these results, a family of peptides derived from the Kunitz domain of human proteins was selected and called Angiopeps. These peptides have higher apparent brain volume of distribution than aprotinin. Among them, Angiopep-2 was selected and further characterized.

Other peptides have been proposed as a drug delivery system, such as the polybasic peptides SynB1, SynB4, and peptides derived from Antennapedia and PD-TAT proteins from human immunodeficiency virus (Drin et al., 2003; Dietz and Bahr, 2004; Peng et al., 2004). These peptides are highly positively charged, and absorptive-mediated transcytosis has been proposed for their transport across the BBB. A bradykinin analog [H-Arg-Pro-Hyp-Gly-Thi-Ser-Pro-4-Me-Tyr(psi CH2NH)-Arg-OH or Cereport] has also been reported to increase the penetration of small molecules such as carboplatin by transitory opening of the BBB (Borlongan and Emerich, 2003). The exact molecular mechanism of Angiopep transcytosis remains to be established. However, the fact that these peptides are derived from aprotinin and human proteins known to interact with the LDL receptor related protein family (LRP1 or LRP2, also known as megalin) and that they contain a fragment responsible for the interaction with these receptors suggest a receptor-mediated transport mechanism.
for aprotinin and Angiopeps. The decrease by approximately 50% in the \( V_d \) of \(^{125}\text{I}\)-Angiopep-2 in the presence of excess unlabeled Angiopep-2 (10 \( \mu \)M) suggests also that a part in the transport of this peptide is associated with a receptor. This is in agreement with the inhibition of \(^{125}\text{I}\)-urokinase-plasminogen activator inhibitor-1 complex to LRP1 and LRP2 by aprotinin, which has been reported to be in the same range (4 \( \mu \)M) (Moestrup et al., 1995). In addition, partial inhibition of aprotinin and Angiopep-2 transcytosis by RAP, which was previously shown to inhibit the binding of all ligands to all members of the LDL-family receptor, also indicates that the passage of both molecules across brain endothelial cells involves LRP-mediated events.

These are the first results showing that peptides derived from human Kunitz domains could be used as a potential delivery system for macromolecules. To date, various attempts have been made to identify and characterize an efficient drug delivery approach for the brain (Demeule et al., 2004; de Boer and Gaillard, 2007; Pardridge, 2007a). Different strategies are now under investigation for peptide and protein drug delivery to the brain. Invasive procedures include the direct intraventricular administration of drugs by means of surgery, and the temporary disruption of the BBB via intracarotid infusion of hyperosmolar solutions (Doolittle et al., 2000; Hall et al., 2006). Pharmacologically based strategies include facilitating passage through the BBB by increasing the lipid solubility of peptides or proteins (Zhou et al., 2002). Physiologically based strategies exploiting the various carrier mechanisms at the BBB have been characterized in the recent years (Pardridge, 2006, 2007b). In this approach, drugs are attached to a protein vector that performs like a receptor-targeted delivery vehicle at the BBB. This approach is highly specific and presents high efficacy with extreme flexibility for clinical indications with unlimited targets. Overall, the results obtained in the present study with aprotinin and Angiopep suggest that their transcytosis involves a member of the LDL-receptor family. These receptors are known to share various ligands and protein complexes of high molecular weight (Hussain et al., 1999; May et al., 2007). Thus, our data suggest that these receptors could be advantageously used to transport small molecules, and high-molecular-weight peptides or proteins such as therapeutic monoclonal antibodies, across the BBB.

In conclusion, these are the first in vitro and in vivo results showing that aprotinin and aprotinin-derived peptides have a higher ability to accumulate in the brain than other proteins such as transferrin and RAP. Taken together, our results indicate that Kunitz-derived peptides could be advantageously used as a new brain delivery system. Further work is now underway with various therapeutic targets, including
