ABSTRACT

The majority of kidneys used for transplantation are obtained from deceased donors. These kidneys must undergo cold preservation/storage before transplantation to preserve tissue quality and allow time for recipient selection and transport. However, cold storage (CS) can result in tissue injury, kidney discardment, or long-term renal dysfunction after transplantation. We have previously determined mitochondrial superoxide and other downstream oxidants to be important signaling molecules that contribute to CS plus rewarming (RW) injury of rat renal proximal tubular cells. Thus, this study’s purpose was to determine whether adding mitoquinone (MitoQ), a mitochondria-targeted antioxidant, to University of Wisconsin (UW) preservation solution could offer protection against CS injury. CS was initiated by placing renal cells or isolated rat kidneys in UW solution alone (4 h at 4°C) or UW solution containing MitoQ or its control compound, decyltriphenylphosphonium bromide (DecylTPP) (1 μM in vitro; 100 μM ex vivo). Oxidant production, mitochondrial function, cell viability, and alterations in renal morphology were assessed after CS exposure. CS induced a 2- to 3-fold increase in mitochondrial superoxide generation and tyrosine nitration, partial inactivation of mitochondrial complexes, and a significant increase in cell death and/or renal damage. MitoQ treatment decreased oxidant production ~2-fold, completely prevented mitochondrial dysfunction, and significantly improved cell viability and/or renal morphology, whereas DecylTPP treatment did not offer any protection. These findings implicate that MitoQ could potentially be of therapeutic use for reducing organ preservation damage and kidney discardment and/or possibly improving renal function after transplantation.

Introduction

Deceased organ donors have provided a substantial number of kidneys for patients suffering from end-stage renal disease who require transplantation. These kidneys must undergo cold preservation before transplantation. The preferred method of organ preservation in the United States is cold storage (CS), which is used in approximately 80% of transplantation cases (Maathuis et al., 2007; Moers et al., 2009). CS slows down metabolic reactions to preserve organ quality while allowing time for recipient selection and transport. Although this procedure is extremely valuable, CS has been shown to cause vasoconstriction, tubular and endothelial injury, and cell death (Salahudeen et al., 2001, 2004), which can result in kidney discardment. Based on the 2009 Organ Procurement and Transplantation Network/Scientific Registry of Transplant Recipients Annual Report, 16% of kidneys recovered from potential deceased donors were discarded because of cold ischemia times, biopsy findings, or the inability to locate a recipient (Klein et al., 2010). Kidneys that are transplanted after CS, compared with kidneys from living donors, can lead to delayed graft function, chronic allograft nephropathy, graft loss, and/or increased medical cost (Ojo et al., 1997; Wight et al., 2003; Schwarz et al., 2005). Because of these CS outcomes, it is imperative to determine

ABBREVIATIONS: CS, cold storage; RW, rewarming; DecylTPP, decyltriphenylphosphonium bromide; I/R, ischemia/reperfusion; LDH, lactate dehydrogenase; MitoQ, mitoquinone; NOS, nitric-oxide synthase; NRK, normal rat kidney; ROS, reactive oxygen species; UW, University of Wisconsin; TUNEL, terminal deoxynucleotidyl transferase dUTP nick end labeling; DMEM, Dulbecco’s modified Eagle’s medium; FCS, fetal calf serum; Untx, untreated; PBS, phosphate-buffered saline; TdT, terminal deoxynucleotidyl transferase.
additional strategies to enhance the quality of deceased donated kidneys during preservation.

Many research groups have made significant advances in this area by testing a range of compounds as additives to preservation solutions to improve cellular or tissue function during CS or after transplantation. Some reports suggest that the addition of bioflavonoids and trophic factor supplementation to preservation solutions should be explored further because these compounds prevented lipid peroxidation, mitochondrial dysfunction, and loss of cell viability during CS of porcine and canine renal tubular cells (Ahlenstiel et al., 2006; Kwon et al., 2007). The addition of polyethylene glycol and trimetazidine to preservation solutions reduced interstitial and peritubular inflammation, infiltration, and renal dysfunction of pig kidneys after cold ischemia/reperfusion (I/R) (Hauet et al., 2000; Faure et al., 2002). The addition of the antioxidant deferoxamine to the University of Wisconsin (UW) preservation solution has been shown to improve glomerular filtration rate and decrease cell death in a syngeneic rat kidney transplant model (Huang et al., 2003). Despite these efforts and other highly regarded findings, only polyethylene glycol has been reported to improve kidney preservation in a preliminary clinical study (Codus et al., 2009).

The aim of the present study was to determine whether adding mitoquinone (MitoQ), a mitochondria-targeted antioxidant, to UW preservation solution could ameliorate early CS (4 h) injury using rat renal proximal tubular cells and isolated rat kidneys. MitoQ is comprised of a ubiquinone moiety covalently linked to an aliphatic 10-carbon chain terminating with a triphenylphosphonium cation (Kelso et al., 2001). Once localized to the mitochondria, it is reduced to the active antioxidant ubiquinol by complex II of the electron transport chain. In preventing oxidative damage, it is oxidized to ubiquinone, which is then re-reduced by complex II (James et al., 2005). MitoQ has been shown to be beneficial against oxidative stress, mitochondrial dysfunction, and cell death in cellular and animal models of sepsis, cardiac I/R, and cardiac hypertrophy (Adlam et al., 2005; Lowes et al., 2008; Graham et al., 2009). In addition, MitoQ has been tested in two phase II clinical trials where it was shown to reduce liver damage in patients with chronic hepatitis C virus infection (Gane et al., 2010; Snow et al., 2010).

MitoQ was selected for this study because it is directly targeted to the mitochondria where we believe the initiating events of CS injury occur. We have reported mitochondrial reactive oxygen species (ROS; superoxide, nitric oxide, and peroxynitrite) to be major contributors to mitochondrial dysfunction and oxidant production during 24-h CS and 6-h rewarming (RW) of rat renal proximal tubular cells (Mitchell et al., 2010). Consequently, this seems to be the first report evaluating the benefits of adding a mitochondria-targeted antioxidant to an organ preservation solution. In addition, a control compound, decyltriphenylphosphonium bromide (DecylTPP), which has a similar chemical structure to MitoQ but without the antioxidant ubiquinol moiety, was included in this study to determine whether the effects of MitoQ were solely caused by its antioxidative properties. Our results reveal that adding MitoQ to UW preservation solution provides significant protection against oxidative stress, mitochondrial dysfunction, cell death, and renal injury during CS of rat renal proximal tubular cells and rat kidneys.
**Mitochondrial Superoxide Production.** MitoSOX Red (Invitrogen) was used to measure mitochondrial superoxide generation during CS. In brief, cells were preloaded in the dark with MitoSOX red (5 μM; 10 min at 37°C) before treatment (groups 1–4). Fluorescence was visualized using an Eclipse E800 microscope (Nikon, Melville, NY) with a rhodamine filter using a water immersion objective (60×). Fluorescent images of NRK cells were captured with equal exposure times and quantified by averaging the mean intensity fluorescence of five random cells in three different fields using Nikon Nis Elements software. In separate experiments, cells were grown on coverslips, preloaded with MitoSOX Red before treatment (groups 1–4), and evaluated for mitochondrial superoxide generation using a Hitachi F-2500 spectrophotometer (Hitachi, Tokyo, Japan) equipped with a coverslip holder using two different excitation wavelengths: 396 and 510 nm with the emission measured at 580 nm as described previously (Munussamy and MacMillan-Crow, 2009). In addition, rat kidneys were monitored for mitochondrial superoxide generation by flushing kidneys with saline through the aorta using a small catheter as described under Cold Storage Ex Vivo Model, followed by saline containing MitoSOX Red (5 μM; 10 ml/kidney) before treatment (groups 1–4). Paraffin sections were analyzed using the rhodamine filter on the Nikon Eclipse 800 microscope (20×).

**Nitrotyrosine Immunocytochemistry and Immunohistochemistry.** NRK cells (groups 1–4) were assessed for nitrotyrosine formation as described previously (Mitchell et al., 2010). In brief, cells were immunostained with nitrotyrosine polyclonal antibody (1:200; Millipore, Billerica, MA), Alexa-594-conjugated antibody (1:1000; Invitrogen), and 6-diamidino-2-phenylindole (1:100; Invitrogen) for nuclear counterstaining. Positive controls were cells treated with peroxynitrite (0.8 mM) in PBS for 5 min at room temperature. Negative controls were cells treated with peroxynitrite, but the antibody binding specificity was confirmed by blocking the nitrotyrosine antibody with excess 3-nitrotyrosine (10 mM; Sigma-Aldrich, St. Louis, MO). Nitrotyrosine staining was evaluated and captured with equal exposure times using a Nikon Eclipse 800 microscope (40× oil). Images were quantified by averaging the mean intensity fluorescence of five random cells in three different fields using Nikon Nis Elements software. Renal tissue sections were assessed for the presence of nitrotyrosine protein adducts by nitrotyrosine immunohistochemistry. Tissue sections were deparaffinized and rehydrated, followed by antigen retrieval (20-min incubation at 95°C with 10 mM sodium citrate buffer, pH 6.0; Sigma-Aldrich). Sections were blocked with peroxidase suppressor (Thermo Scientific, Rockford, IL) and DAKO protein block (Dako North America, Inc., Carpinteria, CA) and incubated overnight at 4°C with the polyclonal rabbit antinitrotyrosine antibody (1:3000). Sections were developed using the DAKO LSAB+System-HRP kit (Dako North America, Inc.) followed by Mayer’s hematoxylin counterstaining (Electron Microscopy Sciences, Hatfield, PA), dehybridization, and mounting with Cytoseal-60 (Electron Microscopy Sciences). The specificity of nitrotyrosine antibody binding in the renal tissue was confirmed by blocking the antibody with 3-nitrotyrosine (10 mM).

**Mitochondrial Respiratory Complex Activity.** NRK cell and rat kidney mitochondria were isolated by centrifugation on a sucrose density gradient. The activity of mitochondrial respiratory complexes I, II, III, or IV were assayed spectrophotometrically using 100 μg of mitochondrial protein at 30°C as described previously (Birch-Machin and Turnbull, 2001; Saba et al., 2008).

**Morphological Assessments.** Renal sections were assessed for tissue injury using the periodic acid-Schiff reaction. Tissues were deparaffinized and rehydrated, followed by oxidation with 0.5% periodic acid solution (Sigma-Aldrich) for 5 min at room temperature. Sections were rinsed with distilled water and incubated with Schiff reagent (Sigma-Aldrich) for 15 min at room temperature. Subsequently, sections were washed with tap water, counterstained with Mayer’s hematoxylin, dehydrated, and mounted with Cytoseal-60. Morphological evaluation of tubular dilation, brush border loss, and cellular debris/tubular cast formation were performed blindly with light microscopy and assessed semiquantitatively according to the following scoring system: 0, no changes; 1, mild changes; 2, moderate changes, and 3, severe changes.

**Cell Death Measurement.** Cell cytotoxicity was determined using the LDH-Cytotoxicity Assay Kit II (Biovision Research Products, Mountain View, CA) according to the manufacturer’s instructions. Absorbance was measured at 450 nm using a SpectraMax 190 microplate reader and SpectraMax software (Molecular Devices, Sunnyvale, CA). Renal cell death was determined using TUNEL staining. Kidney sections were deparaffinized, rehydrated, and exposed to antigen retrieval (20-min incubation at 95°C with 10 mM sodium citrate buffer, pH 6.0) followed by washing with distilled water and quenching of endogenous peroxidase. Sections were immersed in TdT labeling buffer and then incubated in a humidified chamber with the labeling reaction mix from the TACS 2 TdT-DAB In Situ Apoptosis Detection kit (Trevigen, Inc., Gaithersburg, MD) for 1 h at room temperature. The reaction was stopped with TdT stop buffer, and slides were subsequently washed with PBS. Sections were incubated for 10 min with streptavidin-HRP followed by development with diaminobenzidine solution, counterstaining with Mayer’s hematoxylin, dehydration, and mounting with Cytoseal-60. The amount of cell death was calculated by averaging the number of cells positive for TUNEL (brown staining) in 10 different fields (cortex and medulla) (20×). All images were taken at equal exposure times (40× oil).

**Statistical Analysis.** Results are presented as mean ± S.E.M. Means were obtained from three (in vitro) or five (ex vivo) independent experiments. One-way analysis of variance was used to compare the mean values among the untreated/controls and treatment groups, followed by Tukey’s test to compare differences in mean between two groups at 95% level of confidence using Origin 6.0 statistical software (OriginLab, Northampton, MA). Differences with a P value less than 0.05 was considered statistically significant.

**Results**

**Protective Effect of MitoQ on Mitochondrial Superoxide Generation during CS.** The optimal doses for MitoQ and DecylTPP treatment were selected from dose-response experiments during 4-h CS. For the cellular-based studies, 1 μM was chosen from a range of 0.5, 0.75, 1.0, 1.5, and 2 μM, whereas the most efficacious dose for the ex vivo studies was 100 μM from a dose-response study of 50, 100, and 500 μM (data not shown). The potential protective benefits of MitoQ treatment against CS injury were tested initially using MitoSOX Red, a mitochondrial-targeted fluorescent dye that measures mitochondrial superoxide generation. As shown in Fig. 2A, NRK cells exposed to CS resulted in a 2-fold increase in fluorescence due to mitochondrial superoxide compared with untreated cells. MitoQ offered significant protection against CS-induced mitochondrial superoxide generation; whereas the control compound DecylTPP did not offer any protection. This was further confirmed using a spectrophotometric-based assay detecting MitoSOX Red fluorescence excitation at 396 and 510 nm, where 396 nm is a specific indicator of mitochondrial superoxide, and 510 nm detects nonspecific oxidant generation (Robinson et al., 2006) (Fig. 2B). In addition, kidneys exposed to CS alone displayed increased mitochondrial superoxide generation compared with control kidneys (Fig. 2C). MitoQ treatment markedly decreased mitochondrial superoxide generation, whereas kidneys treated with DecylTPP had comparable levels of mitochondrial superoxide to kidneys exposed to CS alone (Fig. 2C).
MitoQ Attenuates Nitrotyrosine Adduct Formation during CS.

Immunocytochemistry and immunohistochemistry were used to evaluate nitrotyrosine protein adducts during CS. As shown in Fig. 3A, NRK cells exposed to CS alone had a significant increase in nitrotyrosine staining (red fluorescence) compared with untreated cells. MitoQ attenuated nitrotyrosine formation ∼2-fold, whereas the control compound DecylTPP did not decrease CS-mediated nitrotyrosine formation (Fig. 3A). Peroxynitrite-treated cells had intense nitrotyrosine formation (positive control) and was blocked when the nitrotyrosine antibody was preabsorbed with excess 3-nitrotyrosine (negative control; ONOO⁻ + block). Rat kidney immunohistochemistry data were consistent with the in vitro study findings regarding the effect of MitoQ and nitrotyrosine. Figure 3B shows an in-
crease in nitrotyrosine (brown staining) in the distal and proximal tubules and to a lesser extent in the glomeruli of CS kidneys compared with control kidneys. Kidneys treated with MitoQ had less nitrotyrosine formation. In contrast, DecylTPP-treated kidneys had similar amounts of nitrotyrosine compared with CS kidneys. The specificity of nitrotyrosine staining was also confirmed using antibody preabsorbed with excess 3-nitrotyrosine (CS block).

**MitoQ Prevents Mitochondrial Respiratory Complex Inactivation during CS.** Mitochondrial respiratory com-
plex activity was evaluated in both the in vitro and ex vivo renal models to investigate whether 4-h CS alters mitochondrial respiratory function. Complexes I and II were significantly inactivated after CS of NRK cells compared with untreated cells (Fig. 4). MitoQ completely prevented complex I and II inactivation, whereas DecylTPP had no significant effect on complex activity. Complexes III and IV were not assessed in this study because we have previously shown both complex activities to be unchanged with 24-h CS (Mitchell et al., 2010); therefore evaluation of these complex activities was not warranted. Consistent with the in vitro findings, CS of rat kidneys led to partial inactivation of complexes I and II activity and had no effect on complexes III and IV (Fig. 4). MitoQ protected against complex I and II inactivation of CS kidneys, whereas DecylTPP did not have any effect.

CS Induced Renal Injury and Cell Death Is Decreased with MitoQ Treatment. Periodic acid-Schiff staining was performed to examine histopathological changes during CS of rat kidneys. Significant widespread tubular damage such as dilation, brush border loss, and cellular debris/cast formation occurred with CS exposure (Fig. 5A). MitoQ improved renal histology significantly, whereas DecylTPP treatment did not reverse renal injury. TUNEL staining, indicated by brown staining of the nuclei, was used as a marker of cell death. As shown in Fig. 5B, CS led to a significant increase in cell death (red arrows) compared with control kidneys. MitoQ treatment decreased cell death by ~2-fold compared with CS kidneys, whereas DecylTPP offered no protective benefits against cell death.

MitoQ Decreases Nitrotyrosine Formation and Cell Death during CS Plus Rewarming of NRK Cells. To test whether MitoQ could potentially offer protection against oxidant production and cell death after reperfusion/transplantation, cells were exposed to CS plus RW. As shown in Fig. 6A, 4-h CS plus overnight (18 h) RW of NRK cells resulted in significant nitrotyrosine formation. Adding MitoQ during CS attenuated nitrotyrosine staining significantly during CS>RW, whereas the control compound DecylTPP had no effect. LDH cytotoxicity revealed a significant increase in cell death of NRK cells exposed to CS>RW compared with untreated cells (Fig. 6B). MitoQ decreased cell death approximately 2-fold during CS alone and CS>RW. DecylTPP did not reduce cell death in either treatment group.

Discussion

In the present study, we have demonstrated that adding the mitochondria-targeted antioxidant MitoQ to UW preservation solution decreases oxidant production, prevents mitochondrial dysfunction, and minimizes renal injury and cell death during CS of NRK cells and isolated rat kidneys. MitoQ’s control compound, DecylTPP (the lipophilic cation that targets MitoQ to the mitochondria), offered no protective effect and was included in this study as a negative control and to confirm MitoQ’s antioxidative properties. It is important to point out that MitoQ was administered only during CS (4°C) throughout this study. Thus, it is an ideal drug candidate for improving organ preservation because it would not require administration to the deceased donor before explantation or during organ reperfusion of the transplant recipient. During cold preservation of human organs, biopsies that evaluate renal damage are often used to determine whether to transplant or discard a donated kidney. Therefore, MitoQ’s ability to reduce histological evidence of renal injury suggests that MitoQ might lead to fewer kidneys being discarded because of CS-mediated damage. Moreover, MitoQ has been proven to be safe and well tolerated in two phase II clinical trials for Parkinson’s disease and hepatitis C virus (Gane et al., 2010; Snow et al., 2010), which could expedite its testing in clinical trials for use during organ preservation. In addition, MitoQ would not be administered systemically to patients, so potential drug-induced side effects would be greatly minimized. Results from the present study using markers of oxidative stress, mitochondrial function, and cellular injury provide substantial evidence of the effectiveness of MitoQ against CS-mediated injury and support the notion that mitochondrial ROS should be an important target in preventing cold preservation injury of donated kidneys.

Previous studies using human and porcine renal tubular cells have shown ROS, including superoxide (NADPH oxidase as the source), hydrogen peroxide, and hydroxyl radical to be major contributors to CS injury (Salahudeen et al., 2000; Karhumäki et al., 2007). We recently reported mitochondrial ROS (superoxide, nitric oxide, and peroxynitrite) to be signaling molecules that contribute to mitochondrial dysfunction and cell death of rat renal tubular cells exposed to CS (24 h) plus RW (6 h) (Mitchell et al., 2010). It is important to point out that this previous study measured CS injury at a later time point (24 h) because most donated kidneys are preserved for extended periods. In the present study, CS events were measured at 4 h to determine how early renal and mitochondrial injury occurs and to establish whether preventing early CS-mediated injury could avert downstream toxic events.

MitoQ’s potential protective effects during CS were initially tested by measuring mitochondrial superoxide generation using MitoSOX Red. CS-induced mitochondrial superoxide was significantly reduced with MitoQ treatment, suggesting MitoQ would be highly effective in reducing downstream oxidant production and injury. Previous reports have shown MitoQ to decrease mitochondrial ROS specifically derived from superoxide in a hyperglycemic endothelial cell model and fenretidine-treated neuroblastoma cell lines (Quijano et al., 2007; Cuperus et al., 2010). In the latter study, fenretidine treatment induced apoptosis of neuroblastoma tumors by increasing mitochondrial ROS production. Superoxide is the proximal oxidant that leads to the formation of other deleterious oxidants and can cause additional damage within the cell by entering the intermembrane space through the mitochondrial transition pore and/or through the voltage-dependent anion channel (Turrens, 2003).

Nitric oxide is a free radical that is well known to interact with superoxide to form peroxynitrite. It is generated by nitric-oxide synthase (NOS) and is an important signaling molecule in many physiological processes. Few reports have evaluated the effect of cold ischemia alone on NOS protein levels or activity. Desrois et al. (2005) reported endothelial NOS protein levels to decrease significantly during cold ischemia and NOS activity to initially increase after 3-h ischemia but significantly declined after 6-h cold ischemia in a heterotopic rat heart transplantation model. Those authors suggested that cold ischemia induced endothelial dysfunction in the rat heart by decreasing nitric oxide’s ability to exert its...
Fig. 4. MitoQ prevents mitochondrial respiratory complex inactivation during CS. Individual mitochondrial respiratory complex activities were measured using isolated mitochondria from NRK cells (A and B) and isolated rat kidney mitochondria (C-F) exposed to CS, CS + MitoQ, or CS + DecylTPP (1 µM in vitro and 100 µM ex vivo). Values are expressed as percentage mean ± S.E.M. (n = 3 in vitro or 5 ex vivo) of respective controls (set to 100). **, P < 0.01 or ***, P < 0.001 compared with respective controls. †, P < 0.05 compared with CS.
Fig. 5. Effect of MitoQ on CS-induced renal injury and cell death. Representative photomicrographs from five animal experiments are shown. A, periodic acid-Schiff staining of rat kidneys (left to right): control, CS, CS + MitoQ (100 μM), and CS + DecylTPP (100 μM) (20×). Extensive tubular dilation, brush border loss, and cellular debris/tubular cast formation were observed and assessed blindly and semiquantitatively according to the following scoring system: 0, no changes; 1, mild changes; 2, moderate changes; and 3, severe changes. B, TUNEL staining (brown nuclei; red arrows) of rat kidneys (left to right): control, CS, CS + MitoQ (100 μM), and CS + DecylTPP (100 μM) (40×). The amount of cell death was calculated by averaging the number of cells positive for TUNEL in 10 different fields of the cortex and medulla. Values are expressed as mean ± S.E.M. (n = 5). ***, P < 0.001 compared with control. †, P < 0.05 compared with CS.
protective effects. In our recent article, available nitric-oxide levels declined significantly after 24 h CS of NRK cells, which was probably caused by nitric oxide interacting with mitochondrial superoxide to form peroxynitrite (Mitchell et al., 2010). The fact that the NOS inhibitor N5-[imino(methylamino)methyl]-L-ornithine citrate inhibited nitrotyrosine staining (one marker of peroxynitrite) strongly suggests that nitric oxide was indeed formed, but was quickly converted to peroxynitrite by interacting with superoxide. Additional studies using the CS NRK cell model showed that available nitric-oxide levels were also decreased after 4-h CS, and MitoQ had no effect (data not shown).

MitoQ’s effectiveness against CS-induced mitochondrial superoxide warranted further evaluation of tyrosine nitration during CS of NRK cells and isolated rat kidneys. Formation of nitrotyrosine can adversely affect protein function and additional cellular processes. We have determined previously that cold I/R of rat kidneys resulted in nitrotyrosine formation (Saba et al., 2008), and based on our current findings we suggest that cold storage alone increases tyrosine nitration. MitoQ was able to markedly reduce nitrotyrosine in both the cellular and isolated kidney models. After detoxifying oxidants, MitoQ can be reduced by the respiratory chain to be repeatedly recycled back to its antioxidant form (James et al., 2005), which further supports the advantage of adding MitoQ during CS because it is able to continuously scavenge oxidants. Taken together, our data suggest that adding MitoQ to UW solu-
tion attenuates oxidative stress during CS by scavenging mitochondrial superoxide.

Increased oxidative production can lead to mitochondrial respiratory complex inactivation, decline in adenosine triphosphate levels, mitochondrial dysfunction, and consequently cell death (Fosslien, 2001). Cold preservation has been shown to impair mitochondrial function in many organ systems (Meng et al., 1991; Salahudeen et al., 2003; Kuznetsov et al., 2004). Our data reveal that CS leads to partial inactivation of mitochondrial complexes I and II in both the cellular and ex vivo kidney models and excitingly was completely prevented with MitoQ treatment. Protecting complex I and II activity is important because these complexes initiate oxidative phosphorylation and can generate additional oxidants once inactivated. MitoQ has been shown to restore mitochondrial function in a rodent model of cardiac dysfunction induced by sepsis (Supinski et al., 2009). Those authors previously determined that cardiac mitochondrial dysfunction in this model was associated with a significant increase in ROS generation. Thus, MitoQ’s ability to restore CS respiratory complex activity could explain the reduction in mitochondrial superoxide generation also observed with MitoQ.

Both cold ischemia-mediated oxidant production and mitochondrial dysfunction can lead to irreversible renal injury and cell death that can result in further damage once the organ is transplanted. It has been shown that loss of tubular brush border is a clear indicator of ischemic injury and a sign of impaired proximal tubular function (Venkatachalam et al., 1978), which can ultimately lead to cell death. In the current study, MitoQ protected against CS-mediated renal injury by decreasing tubular brush border loss, tubular dilation, and cell death. Unfortunately, we do not have the surgical expertise to transplant CS kidneys into a rat recipient to evaluate renal function after transplantation. However, the extent of protection observed with MitoQ during CS alone clearly indicates that renal function would most likely be improved, and as mentioned earlier protection during CS alone could translate into fewer kidneys being discarded. Future studies, via a collaborative effort, will be performed in a porcine renal model of CS followed by transplantation to address whether MitoQ can attenuate injury after transplantation. This larger animal model is more clinically relevant and technically easier for surgical transplantation studies to be executed. Nevertheless, we were able to measure the benefits of MitoQ treatment against nitrotyrosine formation and cell death after CS and subsequent RW of NRK cells, which is a respectable model that simulates what occurs at the cellular level after rewarming/reperfusion (Stec et al., 2007; Waller et al., 2007). We recently showed that CS alone (24 h) increased superoxide and nitrotyrosine levels with minimal cell death, whereas RW NRK cells increased cell death significantly (Mitchell et al., 2010). These data were similar to what we show in the current article at an earlier time point and importantly how MitoQ treatment protected against this injury. Collectively, these findings suggest that the mechanisms leading to cell death during CS,RW seem to be initiated during CS alone and can be modulated with antioxidant treatment.

In summary, this is the first report showing that mitochondrial superoxide increases significantly during early CS and contributes to mitochondrial and renal damage. We have identified the mitochondria-targeted antioxidant MitoQ to significantly protect against CS-mediated oxidative stress, mitochondrial dysfunction, cell death, and renal injury of renal proximal tubular cells and isolated rat kidneys. These findings suggest that infusion of MitoQ to kidneys before transplantation may be of therapeutic use to reduce CS damage, improve outcome for transplant recipients, and also increase the numbers of donated organs available for transplant, all of which could lead to a decline in health-care costs.
