**ABSTRACT**

Long-term use of opioids is hindered by respiratory depression and the possibility for fatal overdose in drug abusers. This is attributed to higher levels of tolerance that develops against antinociception than to respiratory depression. Identifying important mechanisms that would increase morphine respiratory depression and overdose tolerance could lead to the safer use of opioids. Because protein kinase C (PKC) activity mediates the development and maintenance of morphine antinociceptive tolerance, we hypothesized that activating PKC\(\alpha\) or PKC\(\varepsilon\) at the pre-Bötzinger complex (preBo\(\ddot{c}\)tC) can increase morphine tolerance in respiration and overdose. Laser microdissection and quantitative reverse transcriptase-polymerase chain reaction were used to compare the relative mRNA abundances of PKC\(\alpha\), \(\gamma\), and \(\varepsilon\) between ventrolateral periaqueductal gray (vlPAG) and preBo\(\ddot{c}\)tC. To test whether PKC\(\alpha\) or \(\varepsilon\) could enhance morphine tolerance in respiratory depression and overdose, lentivirus carrying the wild type, constitutively activated mutants, and small interference RNA against PKC\(\alpha\) or \(\varepsilon\) was stereotaxically injected into the preBo\(\ddot{c}\)tC. Expression of constitutively active PKC (CAPKC)\(\alpha\) or \(\varepsilon\), but not wild-type PKC (WTPKC)\(\alpha\) or \(\varepsilon\), at the preBo\(\ddot{c}\)tC allowed rats to develop tolerance to morphine respiratory depression. In terms of lethality, expression of WTPKCe, CAPKCe, or CAPKC\(\varepsilon\) at preBo\(\ddot{c}\)tC increased morphine tolerance to lethal overdose. CAPKCe-expressing rats developed the highest level of respiratory depression tolerance. Furthermore, when CAPKC\(\varepsilon\) lentivirus was injected into the vlPAG, rats were able to develop significant antinociceptive tolerance at low doses of morphine that normally do not cause tolerance. The approach of increasing morphine respiratory depression and lethality tolerance by increasing PKC\(\alpha\) or \(\varepsilon\) activity at preBo\(\ddot{c}\)tC could be used to make opioids safer for long-term use.

**Introduction**

Opioids are the most effective analgesics for the treatment of moderate to severe pain, and morphine is the prototypical opiate. The long-term use of morphine is hampered both by the development of analgesic tolerance and the relative lack of tolerance to side effects such as respiratory depression (Marks and Goldring, 1973; Ling et al., 1989; Paronis and Woods, 1997; Athanasos et al., 2006). Moreover, morphine is thought to cause lethality via respiratory depression (White and Irvine, 1999). With long-term use, differential tolerance to morphine analgesia and respiratory depression would decrease the therapeutic index, the ratio between LD\(\text{so}_{50}\) and ED\(\text{so}_{50}\) (White and Irvine, 1999). Therefore, morphine would be less lethal if tolerance to respiratory depression could be increased relative to analgesic tolerance. More than 10,000 people died of unintentional nonheroin prescription opioid overdose in the United States in 2007, and the majority of deaths occurred in long-term opioid users (Hall et al., 2008; Okie, 2010). Thus, there is the need to develop a safer opioid that has similar levels of tolerance to analgesia, respiratory depression, and lethal overdose.

The preBo\(\ddot{c}\)tC initiates respiration rhythm and also mediates opioid-induced respiratory depression (Janczewski and...
Feldman, 2006; Montandon et al., 2011). Somatostatin is both a functional and anatomical marker for preBoTc since abrupt silencing of somatostatin-expressing neurons at the preBoTc results in apnea and death (Stornetta et al., 2003; Tan et al., 2008). preBoTc also stains positive for the μ-opioid receptor (MOR), and microinjection of [β-Ala2,N-Me-Phe4,Gly5-ol]-enkephalin, a MOR agonist, slows down the respiration rate (Gray et al., 1999). Furthermore, preBoTc is involved in mediating an enhanced respiratory drive in response to hypoxic or acidic conditions (Solomon et al., 2000; Krause et al., 2009). preBoTc is sandwiched by Bötzingen complex (BoTc) and parafacial respiratory group/retrotrapezoid nucleus (pFR5/RTN) rostrally and the ventral respiratory group (VRG) caudally—all of them involved in respiration. Morphine is a well known respiratory depressant, and it is thought to cause lethality by depressing respiration (Pattinson, 2008). If cellular responses to morphine at preBoTc can be altered, it might be possible to increase overdose and respiratory depression tolerance during long-term morphine treatment. One such cellular response is the μ-opioid receptor-mediated PKC activation.

PKC activity is required for both the initiation and maintenance of morphine antinociceptive tolerance. Intracerebroventricular injection of PKC inhibitors before long-term morphine administration prevented the development of antinociceptive tolerance (Gabura et al., 2008). After tolerance has developed, intracerebroventricular injection of either nonspecific PKC inhibitor or subtype-specific inhibitors of α, γ, and ε each reversed morphine antinociceptive tolerance (Javed et al., 2004). Inhibiting PKCα has been shown to block MOR desensitization in locus coeruleus neurons, whereas inhibiting PKCε blocked MOR desensitization in HEK293 cells expressing MOR (Bailey et al., 2009; Chu et al., 2010). Furthermore, development of morphine tolerance was attenuated in PKCγ or ε knockout mice (Zeitz et al., 2001; Newton et al., 2007). Therefore, because of preBoTc’s role in initiating respiration, mediating opioid respiratory depression, and chemoreception, we reasoned that if PKC activity at the preBoTc is increased by expressing constitutively active PKC, tolerance to respiratory depression and lethality will be increased. Although several if not all of the classic or novel PKC subtypes could be involved, we decided to examine one classic subtype, PKCα, and one novel subtype, PKCε, in controlling respiratory depression and lethality tolerance.

The reason for choosing these two PKC subtypes over others was also based on their relative abundance within the preBoTc and ventrolateral periaqueductal gray (vPAG) as demonstrated in our current study. By increasing morphine tolerance in respiratory depression and lethal overdose through PKCα or ε activation at the preBoTc, the safety of morphine might be improved.

The effect of increasing PKC activity at preBoTc on morphine respiratory depression and lethality tolerance was tested in this study. Lentiviruses carrying wild type, constitutively active, or small interfering RNA (siRNA) against either PKCα or PKCε were stereotaxically microinjected into the preBoTc bilaterally. Activation of PKCα or ε at preBoTc increased tolerance to morphine respiratory depression and lethality. We observed that rats expressing constitutively activated PKCε (CAPKCe) developed the highest level of tolerance to morphine respiratory depression in terms of the time to onset of tolerance, level of hemoglobin saturation, and fold increase in E_{D_{50}}. We also observed that wild-type PKCε (WTPKCε) expressing rats developed overdose tolerance but not rats that received WTPKCα lentivirus injections. Therefore, there might be PKC subtype selectivity in morphine respiratory depression and lethality tolerance development.

Materials and Methods

Animals. Male Sprague-Dawley rats between 250 and 275 g were purchased from Harlan (Indianapolis, IN). All surgeries and behavioral tests were approved by the University of Minnesota Institutional Animal Care and Use Committee (protocol 0902A00283). Rats were housed in a 12-h light/dark cycle with food and water ad libitum. Only well healed rats were used in subsequent experiments because approximately 25% of rodents either died or suffered neurologic deficits from stereotaxic brain surgery.

Chemicals. Morphine sulfate was obtained from the National Institute on Drug Abuse (Bethesda, MD). Ketamine was purchased from Phoenix Pharmaceuticals (Belmont, CA), xylazine was from Lloyd Laboratories (Shenandoah, IA), isoflurane was from Phoenix Pharmaceuticals, and cefazolin was from Apotex Corporation (Weston, FL). Triton X-100, bovine serum albumin, paraformaldehyde, and iodixanol were purchased from Sigma-Aldrich (St. Louis, MO). Toluidine blue was from Ricca Chemical (Arlington, TX). Advanced Dulbecco's modified Eagle's medium-reduced serum medium, penicillin, and streptomycin were purchased from Invitrogen (Carlsbad, CA).

Cell Culture. NS20Y neuroblastoma cells were grown in advanced Dulbecco's modified Eagle's medium-reduced serum medium (Invitrogen) with 5% fetal calf serum, 100 units/ml penicillin, and 100 μg/ml streptomycin in a 10% CO₂ incubator. For lentiviral transductions, virus was applied at a multiplicity of infection of 500 when the cells were 25% confluent.

Lentivirus Production. Plasmids containing CAPKCe (A25E point mutation), CAPKCe (pseudosubstrate inhibitory site amino acid 154–163 deletion), WTPKCα, and WTPKCε were generously provided by Drs. Allen Samarel and Jody Martin from Loyola University (Maywood, IL) (Strait et al., 2001). Deleting or mutating the pseudosubstrate inhibitory site causes PKCε to become constitutively activated (Pears et al., 1990). WTPKCα and CAPKCe were cloned into the EcoRI sites of the pCDHGFp vector to generate pCDHGFp-WTPKCα and pCDHGFp-CAPKCe (System Biosciences, Mountain View, CA). Correct gene orientation was confirmed by nucleotide sequencing. WTPKCε and CAPKCe plasmids were amplified with primers 5'-TCAAGCTAGCAGCATTGGTAGTTTGGGCCT-3' and 5'-TGTCTCTGTCGTCGAGGATC-3' were either purchased from Open Biosystems (Huntsville, AL, TRCN229759-5'-CCCTATCTTAAACCCCAATCTA-3'; TRCRN22762-5'-CCTGACTTCTGAGAGGTATT-3') or constructed using Invitrogen’s Block-it Pol II RNAi expression kit (5'-AGGTTAAGACCAAAATAATT-3'). Plasmids containing siRNA against PKCα were constructed using Invitrogen’s Block-it Pol II RNAi expression kit (5'-AGGTAAAGACCAAAATAATT-3'). Plasmids containing siRNA against PKCα were either purchased from Open Biosystems (Huntsville, AL, TRCN229759-5'-CCCTATCTTAAACCCCAATCTA-3'; TRCRN22762-5'-CCTGACTTCTGAGAGGTATT-3') or constructed using Invitrogen’s Block-it Pol II RNAi expression kit (5'-AGGTTAAGACCAAAATAATT-3'; 5'-AGAGCTCAATCTGAGAGGTATT-3'; 5'-AGGTTAAGACCAAAATAATT-3'). Vector for scramble siRNA was obtained from Open Biosystems. Fifteen-centimeter plates were coated with polylysine for 15 min at 37°C and washed thoroughly with distilled water. Cells (20 million) were plated on each 15-cm dish 24 h before transfection. All plasmids were harvested using QIAGEN’s Endotoxin-free Plasmid Maxi kits and kept in 0.3 M sodium acetate/ethanol until ready to use (QIAGEN, Valencia, CA).

On the day of transfection, plasmids were ethanol precipitated and dissolved in Tris-EDTA, pH 8.0. Invitrogen’s ViraPower Lentivirus Expression System was used to produce lentivirus (Invitrogen).
Three microliters of Lipofectamine 2000 was used to transfect each microgram of the four-plasmid mixture: pLp1, pLp2, pLP/VSVG, and pCDHGF (ratio 3:1:1:5.5). Supernatants were collected every 24 h for 4 days and stored at 4°C. Cell debris were cleared by centrifuging at 3000 rpm for 5 min and then filtered through 0.45-μm filters (SCHVU01RE; Millipore, Billerica, MA). To concentrate lentivirus, 30 ml of supernatant was put into sterilized ultracentrifuge tubes (Beckman Coulter, Brea, CA), and 200 μl of 60% iodoxilan (Sigma-Aldrich) was layered on the bottom using a metal cannula. After ultracentrifugation for 2.5 h at 4°C, 55,000 g, the virus appeared as a visible band between the clear iodoxilan and red medium. Afterward, medium was removed from the top until the last 3 ml. For larger volumes, ultracentrifugation was repeated until the suspension decreased to less than 30 ml, which underwent a last round of ultracentrifugation for 180 min 4°C at 75,000 g. For larger volumes, ultracentrifugation was repeated until the suspension decreased to less than 30 ml, which underwent a last round of ultracentrifugation for 180 min 4°C at 75,000 g.

To determine LD50 of morphine, Dixon’s up and down method was used. Lethality was defined as death within 24 h of morphine injection. A time of 24 h was chosen as the cutoff for comprehensive ness even though most deaths occurred between 1.5 and 5 h after morphine injection. The LD50 of morphine was determined for both morphine-naive rats and ones that had been chronically treated with 4 days of morphine (5 mg/kg b.i.d.) for a total of eight injections.

Morphine Antinociception. Dixon’s up and down method was used again to determine the ED50 of morphine to elicit antinociception because this approach required fewer animals. Antinociception was measured with the hot-plate test. The hot plate was set to 55°C, and the cut off time was 30 s. Thirty minutes after morphine injection, rats were tested on the hot plate. Licking of the hind paw was deemed a positive nociceptive response. Percentage maximal possible effect (%MPE) was calculated according to the formula: (test latency-baseline latency)/cut off baseline latency) × 100, where >50% MPE was noted as a positive morphine antinociceptive response. This threshold was instituted because Dixon’s up and down method to assess ED50 required a binary outcome of positives and negatives. The threshold of 50% MPE was chosen because it represented robust morphine antinociception. The ED50 of morphine to cause antinociception was determined for both morphine-naive rodents, and rats that were chronically treated with 4 days of morphine (5 or 1.5 mg/kg b.i.d.). Morphine antinociception and respiratory depression were measured in different groups of animals.

Microinjections. For microinjections at the preBöC, rats between 250 and 275 g were anesthetized with 90 mg/kg ketamine and 10 mg/kg xylazine. Depth of anesthesia was monitored every 15 min, and additional doses were given as needed. After mounting on a Stoelting stereotaxic frame (Stoelting, Wood Dale, IL), a mid sagittal incision was made to expose the bregma and lambda. Bregma was positioned 5 mm below lambda, and the muscles on the back of the head were removed to uncover the skull. The connective tissue was cut away with a scissor, and a dental drill cleared away the skull to expose the obex. With obex as zero, coordinates for preBöC were anteroposterior (AP) 0.9 mm, mediolateral (ML) ± 2 mm, and dorsoventral (DV) 2.7 mm (Tan et al., 2008). One microliter of the lentiviral solution was injected on each side over 5 min for a total of two injections, and the cannula was kept in place for another 5 min before withdrawal to prevent backflow (Quintessential Stereotaxic Injector, Stoelting). Viral solution levels in the cannula tubing were marked before and after the injection to confirm virus delivery. For lentivirus microinjections at the vlPAG, four injections of 1 μl each (two injections/side) were made to each rat. Coordinates were AP −8.16 mm and AP −7.44 mm, ML ± 0.8 mm, DV −6 mm with respect to bregma. Four injections were made to cover the entire rostrocaudal extent of vlPAG as the structure is longer in the anterior-posterior axis. Rats received 5 mg/kg i.p. b.i.d. ketoprofen for antinociception and 20 mg/kg i.p. t.i.d. cefazolin for antimicrobial prophylaxis after surgeries.

Immunohistochemistry. Rats were anesthetized with 90 mg/kg ketamine and 10 mg/kg xylazine, perfused with phosphate-buffered saline, and then with 4% paraformaldehyde (Sigma-Aldrich). Brains were postfixed in 4% paraformaldehyde overnight at 4°C, immersed in 30% sucrose until they sank to the bottom, and frozen in OCT (Sakura Finetek, Tokyo, Japan), and 25-μm thick sections were cut.
on a cryostat (Leica Microsystems, Wetzlar, Germany). Brains of rats that died from morphine overdose were removed from the skull, directly frozen in OCT, cut into 25-μm thick sections with a cryostat, and fixed with 4% paraformaldehyde for 3 min before staining. Sections were blocked with 10% normal goat serum (Jackson ImmunoResearch, West Grove, PA), 0.3% Triton X-100 (Sigma-Aldrich), and 0.5% BSA (Sigma-Aldrich) for 1 h at room temperature. All primary antibodies were dissolved in TBS (25 mM Tris, 3 mM KCl, 140 mM NaCl, 0.05% Tween 20, pH 7.4) containing 0.3% Triton X-100 and 0.5% BSA. GFP was stained with mouse anti-GFP 1:1000 (Invitrogen), somatostatin was stained with rabbit anti-somatostatin 1:600 (ImmunoStar, Hudson, WI), and MOR was stained with rabbit anti-MOR 1:10,000 (custom antibody; GeneTex, Irvine, CA). To characterize the rabbit anti-MOR, rat and wild-type mice with cervical spinal cords served as the positive control, whereas MOR knockout mice served as negative control (Supplemental Fig. 1). Sections were incubated with primary antibodies with gentle agitation overnight at 4°C and washed three times, 15 min each. Secondary antibodies were goat anti-mouse Alexa Fluor 488 1:2000 (Invitrogen) and goat anti-rabbit Alexa Fluor 594 1:2000 (Invitrogen) and were diluted in TBS with 0.3% Triton X-100 and 0.5% BSA. Tissue was incubated in secondary antibody for 1 h at room temperature and then washed three times for 15 min each before mounting on slides using FluoroMount-G (SouthernBiotech, Birmingham, AL). Fluorescence images were captured with a Leica DMIRE2 microscope connected to a BD LSR II flow cytometer (BD Biosciences). Fluorescence images were analyzed using FloMax (BioNumerics) software. Additionally, secondary antibody was detected using a goat anti-rabbit Alexa Fluor 594 1:200 (Invitrogen) and were diluted in TBS containing 0.5% BSA. Sections were blocked with 10% normal goat serum (Jackson ImmunoResearch, West Grove, PA), 0.3% Triton X-100, 0.3% G Galacton, 0.05% Tween 20, pH 7.4) containing 0.3% Triton X-100 and 0.5% BSA. Laser light sources from Spectral Applied Research (green: 473 nm; Richmond Hill, ON, Canada). Successful lentivirus transduction was confirmed using immunohistochemical analyses after behavioral studies.

Laser Microdissection and Quantitative Reverse Transcription-Polymerase Chain Reaction. Rats were anesthetized with 5% isoflurane/95%/O2 and decapitated. The brains were immediately removed and frozen in OCT (Sakura Finetek). On the day of microdissection, 8-μm-thick sections were cut with a cryostat, mounted on 2.0-μm-thick polyethylene naphthalate membrane-coated slides (Leica Microsystems), stained with 1% toluidine blue (Rica Chemical, Arlington, TX) for 5 s, fixed in acetone at 4°C for 3 min, and stored on dry ice until microdissection. Laser microdissection was performed with a Leica AS LMD (Leica Microsystems), and mRNA was isolated using TRI Reagent according to manufacturer’s protocol (Molecular Research Center, Cincinnati, OH). Quantitative reverse transcription-polymerase chain reaction (qRT-PCR) was performed using Qiagen’s Quantitect SYBR Green RT-PCR kit and the Bio-Rad iCycler (Bio-Rad, Hercules, CA). qRT-PCR primers to amplify PKCa were 5′-GTGTTACCCGGGCAACGACT-3′ and 5′-GAGGGCAATGGTTGCTTCT-3′; qRT-PCR primers to amplify PKCe were 5′-GACCTGGCCAAGCCACAG-3′ and 5′-GATTTCAGGTGGCAAGCCTCC-3′; qRT-PCR primers to amplify PKCe were 5′-ACGGGCCTCTTGAGAAACTCC-3′ and 5′-AGCTGCTTTGCTGCTAACCCTGTGT-3′; and qRT-PCR primers to amplify keratin were 5′-GACGATATGGAAAGATTGTCGAC-3′ and 5′-AGGACATACAGGGACACACT-3′. To translate Ct values into absolute copy numbers, standard curves were obtained for PKCa, γ, and ε and β-actin mRNA abundance analysis. Using the standard curve, Ct values for each gene was translated into absolute copy numbers, and the copy number was then normalized to the absolute quantity of β-actin. To a minimal degree, cryostat sections from five rats were laser dissected and used in quantification of the transcripts.

Statistical Analysis. Results were analyzed with GraphPad Prism 5 (GraphPad Software Inc., La Jolla, CA). Data is expressed as mean ± S.E.M. Two-way ANOVA with Bonferroni’s post-test was used when there were two factors (i.e., gene and nuclei). One-way ANOVA with Bonferroni’s post-test was used to compare one factor among three or more groups. Student’s t test was used to compare one factor between two groups. P < 0.05 was considered to be statistically significant.

Results

The Relative Level of PKC Subtypes at the vlPAG versus preBo¨tC. Because PKCa, γ, and ε are the three subtypes involved in mediating morphine antinociceptive tolerance (Smith et al., 2007), we decided to compare their relative abundances in the vlPAG and preBo¨tC. The vlPAG is an important center for morphine antinociception, whereas the preBo¨tC is involved in opioid respiratory depression (Sicuti and Advokat, 1987; Lane et al., 2005; Montandon et al., 2011). The relative abundance of the three subtypes at vlPAG versus preBo¨tC might provide some insight into why morphine develops more tolerance in antinociception than respiratory depression or lethal overdose. vlPAG or preBo¨tC was laser microdissected, and the relative quantities of PKCa, γ, and ε mRNAs were determined via qRT-PCR (Supplemental Fig. 2). Standard curves were constructed for each gene to translate Ct values into the copy number. The copy numbers for the three PKC subtypes were normalized to the that of β-actin. Two-way ANOVA analyses indicated that PKC abundances were significantly different \( F_{(6,41)} = 84.21; P < 0.0001 \) (Fig. 1). Bonferroni’s post-tests were used after two-way ANOVA analysis. In vlPAG, PKCe and γ transcripts exist at comparable levels, which are significantly lower than the PKCa abundance (\( P < 0.001 \)). At the preBo¨tC, PKCe was again the highest followed by PKCs, and PKCe was the least abundant subtype (\( P < 0.001 \)). Furthermore, preBo¨tC had more PKCe transcripts than vlPAG (\( P < 0.01 \)), whereas preBo¨tC had less PKCe than vlPAG (\( P < 0.001 \)). PKCe transcripts were present at similar levels in the two nuclei (Fig. 1). Although all three PKC subtypes have been implicated in morphine antinociceptive tolerance development (Smith et al., 2007), we focused on the probable roles of PKC subtypes involved in current studies because these two PKC subtypes represent the classic and novel PKC subtypes, respectively. Furthermore, the higher PKCe levels in vlPAG compared with preBo¨tC (\( P < 0.001 \)) might reflect PKCe’s role on the observed greater morphine tolerance in antinociception than respiratory depression or lethal overdose (Fig. 1).

Lentiviral Expression of PKC at the preBo¨tC. Immunohistochemistry was carried out to confirm transduction of PKC in the preBo¨tC. preBo¨tC is located in the ventrolateral medulla, and somatostatin is both a functional and anatomical marker for preBo¨tC neurons (Stornetta et al., 2003; Tan et al., 2008). GFP delivery by the lentivirus confirms transgene expression in the ventrolateral medulla cells (Fig. 2A). Higher magnification colocalization studies indicated that a subset of GFP-positive cells also expressed the μ-opioid receptor and somatostatin, markers for preBo¨tC neurons (Fig.
PKCα and ε in Morphine Respiration and Overdose Tolerance

PKCc Activation Increases Morphine Respiratory Depression Tolerance. To test whether activating PKCc at the preBötC would increase respiratory depression tolerance, we expressed the constitutively active, wild type, or siRNA against PKCc at preBötC by stereotaxically injecting lentivirus containing the respective genes. Because the siRNA sequences used matched both mouse and rat PKCc mRNA, the ability of lentivirus-delivered PKCc siRNA for knockdown was confirmed both in mouse NS20Y neuroblastoma cells and rat preBötC. Knockdown in rat preBötC was 88.2% compared with GFP (P < 0.001) and 85.6% compared with scrambled siRNA (P < 0.01) [Fig. 4A; F(2,20) = 216.1; P < 0.0001]. To study respiratory depression tolerance, 20 mg/kg morphine was injected intraperitoneally once a day for 5 days, and the Hb Sat was measured. In rats that received GFP, scrambled siRNA, or PKCc siRNA lentivirus at the preBötC, 20 mg/kg morphine consistently depressed Hb saturation below 79% throughout the five daily administrations, indicating a lack of respiration tolerance (Fig. 4B). In contrast, CAPKCC-injected rats started to develop significant tolerance to morphine respiratory depression on the 3rd day with Hb Sat of 91.7% (P < 0.01) [Fig. 4C; F(2,18) = 26.15; P < 0.0001]. CAPKCC also developed tolerance faster than CAPKCA as CAPKCC rats exhibited tolerance from the 4th day instead of the 3rd, similar to CAPKCCs (Figs. 3C and 4C). Alternatively, tolerance can be quantified as increases in ED50, morphine-naive ED50 for respiratory depression was compared with the ED50 after four injections of 20 mg/kg morphine sulfate. Rats that received CAPKCC at preBötC demonstrated a 3-fold increase in respiratory depression ED50 from 16.8 ± 1.8 to 51.4 ± 8.55 mg/kg (P < 0.001) (Fig. 4D). When both were treated with morphine long term, the ED50 of CAPKCC was significantly higher than that of WTPKCC (P < 0.01) [Fig. 4D; F(2,30) = 8.74; P < 0.01]. Injection of GFP, scrambled siRNA, PKCc siRNA, and WTPKCC into preBötC did not result in significant increases in the respiratory depression ED50 after long-term morphine treatment (Fig. 4D). Thus, similar to PKCc, activation of PKCc rather than simple overexpression is needed to cause morphine tolerance in respiratory depression.

PKCa and PKCc Increase Morphine Tolerance to Lethal Overdose. Lethal overdose is the most feared adverse effect during opioid treatment, and respiratory depression is thought to be the cause of morphine lethality (White and Irvine, 1999). Increasing tolerance to overdose would make morphine a safer drug for long-term use. Given that activating PKCo and PKCc increased tolerance to respiratory depression, tolerance to lethal overdose might also be increased. In rats that received GFP, scrambled siRNA, PKCo siRNA, PKCc siRNA, or WTPKCC lentivirus injections at preBötC bilaterally, LD50 did not increase significantly after 4 days of 5 mg/kg b.i.d. morphine. When rats received scrambled siRNA against PKCc at the preBötC, there was a nonstatistically significant decrease in LD50 after long-term use of morphine.
With the same 4 days of 5 mg/kg b.i.d. morphine, rats injected with WTPKCε had their LD50 value increased by 2.02-fold ($P < 0.01$), whereas those injected with CAPKCε and CAPKCε had their LD50 value increased by 2.12- ( $P < 0.001$) and 2.76-fold ($P < 0.001$), respectively, compared with the morphine-naive LD50 values within the same gene [Fig. 5A; $F_{(16,107)} = 6.49; P < 0.001$]. In addition, after long-term morphine treatment, the LD50 of CAPKα was significantly higher than WTPKCα, and the LD50 of CAPKε was higher than WTPKCε ($P < 0.05$) (Fig. 5A). To complement LD50 quantifications, a Kaplan-Meier curve illustrates how GFP and CAPKε-expressing rats survived when injected with increasing doses of morphine. GFP and CAPKε rodents were first treated with 5 mg/kg b.i.d. morphine for 4 days, and then both groups were challenged to increasing doses of morphine each day to measure the percentage survival. CAPKε-expressing rats survived higher doses of morphine than GFP-expressing rats (Fig. 5B). Seventy-eight percent of the rats injected with GFP virus died at 301 mg/kg, and the remaining 22% died when injected with 390 mg/kg the next
day. In contrast, only 43% of CAPKCe-expressing rats died when injected with 301 mg/kg morphine, and the remaining 57% all survived dosage of 645 mg/kg with one rat able to survive dosage of 1071 mg/kg. When morphine caused lethality, most rats died between 1.5 and 5 h after morphine injection.

Expressing CAPKCe at the vlPAG Decreased the Dose Required to Develop Morphine Antinociceptive Tolerance. One possible explanation of why expressing PKC at the preBo¨tC increased tolerance to respiratory depression and lethal overdose is that PKC lowered the threshold to develop tolerance. The threshold required to develop morphine tolerance is different for antinociception versus lethality. In wild-type rats treated with 5 mg/kg b.i.d. morphine for 4 days, the ED50 of morphine to cause antinociception increased 3-fold from 4.04 to 12.87 mg/kg (t = 3.17; P < 0.01), but their LD50 did not change significantly (Fig. 6A and B). Thus, lethality has a higher threshold to develop tolerance than antinociception. Expressing CAPKCe at preBo¨tC might increase tolerance to respiratory depression and lethality by decreasing the threshold to develop tolerance. If this is the case, injection of CAPKCe could also alter tolerance development to morphine’s other effects. Hence, to determine whether CAPKCe is able to decrease the threshold for morphine antinociceptive tolerance development, we injected either saline or CAPKCe lentivirus into the vlPAG (Fig. 6C). When both groups were treated with 1.5 mg/kg b.i.d. for 4 days, only the CAPKCe-expressing rats developed tolerance—ED50 increased 2-fold to 11.9 ± 1.73 mg/kg (P < 0.01) [Fig. 6D; F(4,28) = 20.04; P < 0.001]. Since CAPKCe decreased the threshold to develop morphine tolerance, we sought to investigate whether CAPKCe could further increase tolerance after morphine antinociceptive tolerance developed. Rats given saline injections or CAPKCe at the vlPAG were treated with 5 mg/kg b.i.d. morphine for 4 days, a regimen that results in significant antinociceptive tolerance. Both saline- and CAPKCe-injected rats developed similar levels of antinociceptive tolerance (P > 0.05 for saline and P < 0.01 for CAPKCe) [Fig. 6E; F(4,36) = 22.48; P < 0.0001]. Thus, CAPKCe expression at the vlPAG allowed rats to develop significant antinociceptive tolerance when injected with morphine doses that normally do not cause tolerance, but CAPKCe would not increase the degree of tolerance once antinociceptive tolerance occurred.

Discussion

The hypothesis that activating PKCa or ε at the preBo¨tC could lead to increased morphine tolerance in respiratory depression and lethal overdose was tested. Expression of CAPKCe and ε at preBo¨tC increased morphine tolerance to respiratory depression and lethal overdose. The level of morphine tolerance in respiratory depression was higher in CAPKCe rats than CAPKCe lentivirus-injected rodents. Past studies on PKC’s role in morphine tolerance have focused on inhibiting PKC to decrease antinociceptive tolerance. Our current study is the first report that has investigated PKC’s ability to increase morphine tolerance in respiratory depression and lethal overdose. Because respiration and overdose tolerance is increased, augmenting PKC activity at the preBo¨tC could be one approach to improve the safety of morphine in long-term use.

Fig. 3. PKCa in morphine respiratory depression tolerance. Rats were injected with lentivirus carrying GFP, scramble siRNA, PKCa siRNA, WTPKCa, or CAPKCe at the preBo¨tC bilaterally. A, siRNA knockdown efficiency. After injection of PKCa siRNA lentivirus at the preBo¨tC, PKCa knockdown was assessed through laser microdissection and qRT-PCR. β-Actin was set as 1. *** P < 0.001 for saline and P < 0.01 for WTPKCaε at the vlPAG were decreased compared with saline and CAPKCeε at the vlPAG were decreased compared with CAPKCeε at the vlPAG due to 20 mg/kg morphine. Data were analyzed using two-way ANOVA. ***, P < 0.001 compared with saline and CAPKCeε at the vlPAG were increased compared with CAPKCeε at the vlPAG (two-way ANOVA). Data are presented as mean ± S.E.M. (n ≥ 6).
The goal of this study was to test whether enhancing PKC activity at an important respiration control center could increase tolerance to opioid lethal overdose and respiratory depression. Although the stereotaxic coordinates targeted the preBo\textsuperscript{\textregistered}C, our lentivirus carried the cytomegalovirus promoter, which meant that exogenous PKC expression was not limited to the preBo\textsuperscript{\textregistered}C. Although immunohistochemistry showed that some viral transduced GFP-positive cells also stained for somatostatin and MOR, colocalization was not 100%. Caudal neighbors to preBo\textsuperscript{\textregistered}C include the rostral and caudal VRG. The rostral VRG is involved in inspiration by sending projections to the phrenic nucleus, whereas caudal VRG is implicated in expiration by projecting to expiratory motor neurons (Kirkwood and Sears, 1973; Dobbins and Feldman, 1994). Rostral to preBo\textsuperscript{\textregistered}C are Bo\textsuperscript{\textregistered}C and pFRG/

Fig. 4. PKC\textgreekepsilon in tolerance to morphine respiratory depression. Rats were microinjected bilaterally at the preBo\textsuperscript{\textregistered}C with either lentivirus carrying GFP, scramble siRNA, PKC\textgreekepsilon siRNA, WTPKC\textgreekepsilon, or CAPKC\textgreekepsilon. A, PKC\textgreekepsilon lentiviral siRNA knockdown. In vitro, NS20Y cells were transduced with PKC\textgreekepsilon siRNA lentivirus. In vivo, rat preBo\textsuperscript{\textregistered}C injected with siRNA lentivirus was laser microdissected for qRT-PCR analysis. \textbeta-Actin was set as 1. \*, \(P < 0.05\) and \**, \(P < 0.001\) compared with NS20Y PKC\textgreekepsilon siRNA (one-way ANOVA). \††, \(P < 0.01\) and \†††, \(P < 0.001\) compared with rat preBo\textsuperscript{\textregistered}C PKC\textgreekepsilon siRNA (one-way ANOVA). B and C, respiratory depression due to 20 mg/kg morphine. \*, \(P < 0.001\) compared with day 1 CAPKC\textgreekepsilon. \(n = 6\).

Fig. 5. PKC\textgreekalpha and \textgreekepsilon increase morphine tolerance in lethal overdose. Rats were microinjected with lentivirus carrying GFP only, scramble siRNA, PKC\textgreekalpha siRNA, PKC\textgreekepsilon siRNA, WTPKC\textgreekalpha, WTPKC\textgreekepsilon, CAPKC\textgreekalpha, or CAPKC\textgreekepsilon at the preBo\textsuperscript{\textregistered}C bilaterally. A, morphine LD\textsubscript{50} for naive and chronically treated rats. \*, \(P < 0.05\) compared with chronic WTPKC\textgreekalpha. \**, \(P < 0.001\) compared with naive CAPKC\textgreekalpha. \††, \(P < 0.01\) compared with naive WTPKC\textgreekepsilon. \‡, \(P < 0.05\) compared with chronic WTPKC\textgreekepsilon. \‡‡, \(P < 0.001\) compared with naive CAPKC\textgreekepsilon. Data were analyzed with two-way ANOVA and presented as mean \(\pm\) S.E.M. \(n = 6\). B, survival to increasing doses of morphine. GFP and CAPKC\textgreekepsilon expressing rats were treated with 5 mg/kg b.i.d morphine for 4 days before they were challenged to increasing doses of morphine each day. CAPKC\textgreekepsilon \((n = 7)\) and GFP \((n = 9)\).

The goal of this study was to test whether enhancing PKC activity at an important respiration control center could increase tolerance to opioid lethal overdose and respiratory depression. Although the stereotaxic coordinates targeted the preBo\textsuperscript{\textregistered}C, our lentivirus carried the cytomegalovirus promoter, which meant that exogenous PKC expression was not limited to the preBo\textsuperscript{\textregistered}C. Although immunohistochemistry showed that some viral transduced GFP-positive cells also stained for somatostatin and MOR, colocalization was not 100%. Caudal neighbors to preBo\textsuperscript{\textregistered}C include the rostral and caudal VRG. The rostral VRG is involved in inspiration by sending projections to the phrenic nucleus, whereas caudal VRG is implicated in expiration by projecting to expiratory motor neurons (Kirkwood and Sears, 1973; Dobbins and Feldman, 1994). Rostral to preBo\textsuperscript{\textregistered}C are Bo\textsuperscript{\textregistered}C and pFRG/
RTN. BötC neurons are glycinergic and project to the ventral respiratory group and phrenic nucleus. The inhibitory input from BötC suppresses inspiratory neurons during expiration (Dobbins and Feldman, 1994; Ezure et al., 2003). pFRG/RTN is involved in both expiration and CO2 chemosensation (Janczewski and Feldman, 2006). Dorsal to preBötC is the ambiguous nucleus, which controls muscles of the larynx and pharynx and contains premotor parasympathetic neurons that regulate cardiac function (Dergacheva et al., 2010). Respiratory neurons in the ventrolateral medulla are known to project extensively to each other, and preBötC is known to have reciprocating projections with VRG, BötC, and pFRG/RTN (Ellenberger and Feldman, 1990; Tan et al., 2010). Because many adjacent neurons to preBötC are involved in respiration, unintended viral transduction of preBötC neighbors would still allow us to test the ability of PKC to enhance morphine tolerance to respiratory depression and lethal overdose.

WTPKCα or ε rodents did not develop significant morphine tolerance in respiratory depression; however, but CAPKCα or ε expressing rats did. These results can be explained by the higher PKC activity of the constitutively active mutants. It is well known that deleting or mutating the PKC pseudosubstrate inhibitory region increased PKC activity both in vitro and in vivo as judged by increased translocation to the plasma membrane (Pears et al., 1990; Takeishi et al., 2000). Although µ-opioid receptor-mediated activation of PKC has been reported in cell models (Chu et al., 2010), our current result implies that lower PKC activation by morphine at preBötC could be one of the reasons for less morphine respiration and overdose tolerance than antinociception. At the preBötC, the lack of effect from PCKα and ε siRNA lentivirus indicated that PKC activation was minimal, and PKC might not be an intrinsic mechanism to regulate MOR (Figs. 3, B and D, and 4, B and D). Both CAPKCα and CAPKCε were able to increase respiration and overdose tolerance, and this is in agreement with both subtypes’ role in mediating receptor desensitization after morphine treatment (Bailey et al., 2009; Chu et al., 2010). Whether other members of the classic and novel PKC subtypes would elicit similar responses remains to be demonstrated. In addition, CAPKCε was able to increase respiratory depression tolerance to a higher extent than CAPKCα, which can be caused by differences in kinase activity levels or downstream phosphorylation targets. An
alternative explanation for this difference could stem from the nonspecific promoter, cytomegalovirus, used to drive the expression of the transgenes causing the expression of the constitutively active PKC in nonopioid receptor and nonso-
matostatin expressing neurons (Fig. 2). Whether CAPKCα and CAPKCε were expressed at identical neurons after in-
jection was assumed and not determined.

Several mechanisms have been hypothesized as causing morphine tolerance, and this article investigated PKC be-
cause of the kinase’s role in opioid receptor signaling when morphine was the agonist. Morphine is known to cause PKC activation, which in turn participates in opioid receptor de-
sensitization and tolerance (Smith et al., 2007; Bailey et al.,
2009; Chu et al., 2010). In addition to PKC, β-arrestin medi-
ated opioid receptor desensitization and opioid receptor recycling have been proposed as mechanisms to explain opioid antinociceptive tolerance (He and Whistler, 2005). β-Arrestin 2 knockouts are known to experience less respiratory depres-
sion and constipation than wild-type animals, with single
morphine injections; however, it is not known whether the same applies to long-term treatment or respiratory depres-
sion tolerance (Raehal et al., 2005). More work needs to be
done to determine the effects of β-arrestin and opioid recep-
tor recycling on morphine tolerance in respiratory depression or lethal overdose.

There is correlation between the development of tolerance to morphine respiratory depression and lethality for
CAPKCα and CAPKCε. In contrast, when tolerance did not develop to respiratory depression, such as in WTPKCε,
there was a corresponding lack of tolerance to morphine lethality. This correlation between respiratory depression and lethality agrees with the widely believed idea that respiratory depres-
sion is the main cause of morphine lethality (White and
Irvine, 1999). The majority of morphine lethality occurred
between 1.5 and 5 h after injection, which is later than the
morphine peak effect at 30 min for intraperitoneal injections.
This observation is consistent with the fact that morphine
does not cause complete cessation of breathing even at lethal
doses but a precipitous reduction instead. Although total respiratory arrest would probably cause death close to the
peak effect of morphine at 30 min after injection, a longer
time course is required to cause death when rats are breath-
ing at less than adequate minute ventilation. The cumulated
effect of depressed respiration such as respiratory acidosis
could eventually cause lethality but with slower kinetics than
complete respiratory arrest.

Although therapeutic applicability of the findings in this
article is limited by current technology, our results indicate
that PKCε activation could greatly narrow or equalize toler-
ance between morphine lethality and antinociception. Mor-
phine lethality normally has a higher threshold to develop
than antinociception (Fig. 6, A and B); however, expressing
CAPKCε would lower the threshold and allow morphine lethality tolerance to develop. On the other hand, morphine antinociceptive tolerance would be unchanged as antinociceptive tolerance easily develops, and CAPKCε could not further increase the magnitude of tolerance after it has occurred (Fig. 6E). Equalizing antinociceptive and lethality tolerance would improve the safety of current opioids.

This article tested the hypothesis that selective PKC activ-
ation in preBotC could increase tolerance to morphine res-
piratory depression and lethal overdose. Future opioid ther-
aphetics that take advantage of differences in PKC subtype distribution and morphine-induced PKC activity between an-
aglesics versus respiratory centers could maintain or improve
the therapeutic index of morphine during long-term pain
management. As annual lethal overdoses from prescription opio-
ides have increased to more than 10,000 in the United States, developing approaches to improve the safety of opioids for long-term use is an important health care issue (Okie, 2010).

Acknowledgments

We thank Dr. Martin Wessendorf for the many discussions and
recommendations on this project. We also thank Drs. Allen Samarel
and Martin for kindly providing the PKC subtypes plasmids, Dr. George Wilcox for loaning us the Mouseox, Jinghua Xi for assistance
in producing the rabbit anti-MOR, and Dr. Hui Zheng for technical
assistance in sRNA lentivirus preparation.
