ABT-737 Synergizes with Bortezomib to Induce Apoptosis, Mediated by Bid Cleavage, Bax Activation, and Mitochondrial Dysfunction in an Akt-Dependent Context in Malignant Human Glioma Cell Lines

Received January 6, 2012; accepted March 2, 2012

ABSTRACT

We observed that glioma cells are differentially sensitive to N-[4-[4-(4′-chloro-biphenyl-2-ylmethyl)-piperazin-1-yl]-benzoyl]-4-(3-dimethylamino-1-phenylsulfanylmethyl-propylamino)-3-nitro-benzenesulfonamide (ABT-737) and administration of ABT-737 at clinically achievable doses failed to induce apoptosis. Although elevated Bcl-2 levels directly correlated with sensitivity to ABT-737, overexpression of Bcl-2 did not influence sensitivity to ABT-737. To understand the molecular basis for variable and relatively modest sensitivity to the Bcl-2 homology domain 3 mimetic drug ABT-737, the abundance of Bcl-2 family members was assayed in a panel of glioma cell lines. Bcl-2 family member proteins, Bcl-xL, Bcl-w, Mcl-1, Bax, Bak, Bid, and Noxa, were found to be expressed ubiquitously at similar levels in all cell lines tested. We then examined the contribution of other apoptosis-resistance pathways to ABT-737 resistance. Bortezomib, an inhibitor of nuclear factor-kappaB (NF-κB), was found to enhance sensitivity of ABT-737 in phosphatase and tensin homolog on chromosome 10 (PTEN)-wild type, but not PTEN-mutated glioma cell lines. We therefore investigated the association between phosphatidylinositol 3-kinase (PI3K)/Akt activation and resistance to the combination of ABT-737 and bortezomib in PTEN-deficient glioma cells. Genetic and pharmacological inhibition of PI3K inhibition sensitized PTEN-deficient glioma cells to bortezomib- and ABT-737-induced apoptosis by increasing cleavage of Bid protein, activation and oligomerization of Bax, and loss of mitochondrial membrane potential. Our data further suggested that PI3K/Akt-dependent protection may occur upstream of the mitochondria. This study demonstrates that interference with multiple apoptosis-resistance signaling nodes, including NF-κB, Akt, and Bcl-2, may be required to induce apoptosis in highly resistant glioma cells, and therapeutic strategies that target the PI3K/Akt pathway may have a selective role for cancers lacking PTEN function.

Introduction

Human malignant gliomas are aggressive tumors that generally respond poorly to current therapy with surgery, radiation, and conventional chemotherapy. The molecular basis of their resistance to apoptosis has not been fully elucidated (Hanahan and Weinberg, 2000, 2011; Omuro et al., 2007). In studies using a large-scale short interfering RNA (siRNA) screening approach to identify critical “nodes” for cell death signaling, we identified several targets, including nuclear factor kappaB (NF-κB) and the proteasome, as well as Akt (Thaker et al., 2009, 2010a,b) and Bcl-2 family members (Kitchens et al., 2011) that, when inhibited, promoted apoptotic signaling in glioma cells. Studies from other groups have also indicated that dysregulation of the NF-κB (Bredel et al., 2011), Bcl-2 (Steinbach and Weller, 2004), and Akt (Knobbe et al., 2002) pathways may be integrally involved in mediating glioma resistance to apoptotic signaling. The recent availability of agents to inhibit these targets suggests the application of apoptosis-promoting strategies for therapy-resistant cancers, such as gliomas.

Members of the Bcl-2 family are critical regulators of apoptosis. Interactions between prosurvival and proapoptotic members may determine cell fate, and the balance of Bcl-2 family proteins may confer constitutive and therapy-inducible resistance in gliomas (Bögl er and Weller, 2003). Many cancers, particularly gliomas, are resistant to apoptosis by up-regulation of
antiapoptotic Bcl-2 family members. New anticancer therapeutic agents are being developed to specifically target the prosurvival members of the Bcl-2 family by using small-molecule mimetics of BH3-only proteins. The most prominent among them are the Bcl-2 antagonists N-[4-[(4-chloro-biphenyl-2-yl)methyl]piperazin-1-yl]-benzoyl]-4-(3-dimethy lamino-1-phenylsulfanyl methyl-propylamino)-3-nitro-benzenesulfonamide (ABT-737) and (R)-4-4-[(4-chloro-4,4-dimethyl-3,4,5,6-tetrahydro-[1,1'-biphenyl]-2-yl)methyl]piperazine-1-yl)-N-[(4-[(4-morpholino-1-phenylthio)butan-2-yl]amino)-3-[(trifluoromethyl)sulfonyl] phenyl)sulfonyl]benzamide (ABT-263). ABT-737 binds specifically and with high affinity to the Bcl-2 family of proteins, including Bcl-2, Bcl-xL, and Bcl-W, but not to Mcl-1. As a single agent, however, ABT-737 induces apoptosis in limited tumor types, such as leukemia and lymphomas (Konopleva et al., 2006; Trudel et al., 2007; Vogler et al., 2008; High et al., 2010; Bodet et al., 2011). The reason for varied sensitivities to ABT-737 is not clear.

Bortezomib, a member of a class of agents inhibiting the 20S proteasome, blocks the elimination of diverse cellular proteins targeted for degradation (Adams, 2004). Among its principal effects are the inhibition of NFκB. Bortezomib has been approved by the U.S. Food and Drug Administration for multiple myeloma (Kane et al., 2006), mantle cell lymphoma (Kane et al., 2007), and solid tumors (Aghajanian et al., 2002; Papandreou et al., 2004). Bortezomib has shown increased and/or synergistic activity with several novel targeted agents, indicating its potential to substantially enhance the clinical activity of these novel therapies. We have demonstrated that bortezomib dramatically sensitized glioma cells to tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) (Jane et al., 2011) and vorinostat cytotoxicity (Premkumar et al., 2011), suggesting that this agent may have promise in combination strategies for glioma therapeutics. Other investigators have shown that overexpression of Akt reduced the apoptosis induced by proteasomal inhibitors and TRAIL (Kahana et al., 2011) or histone deacetylase inhibitor (HDACI) (Yu et al., 2008), suggesting that Akt activation may provide a compensatory apoptosis-resistance mechanism in gliomas that may need to be independently infected to achieve maximal therapeutic effects.

Akt is commonly activated constitutively in these tumors by virtue of mutations in PTEN, a tumor suppressor gene located on chromosome 10q23 (Li et al., 1997; Wang et al., 1997) by virtue of mutations in PTEN, a tumor suppressor gene located on chromosome 10; ROS, reactive oxygen species; Smac/DIABLO, second mitochondria-derived activator of caspases/direct inhibitor of apoptosis proteins targeted for degradation (Adams, 2004). Among its principal effects are the inhibition of NFκB. PTEN inactivation in turn leads to the enhanced phosphatidylinositol-3-kinase (PI3K)/Akt pathway (Stambolic et al., 1998). The PTEN gene is frequently deleted or mutated not only in human glioblastoma but also in a wide range of advanced human malignancies, such as prostate, endometrial, breast, lung, kidney, bladder, testis, head, and neck cancers, malignant melanoma, and lymphoma (Li et al., 1997; Steck et al., 1997; Hanahan and Weinberg, 2000, 2011). PTEN inactivation in turn leads to the enhanced phosphorylation and activation of Akt, a cell survival protein kinase that mediates its activity through various downstream effectors, resulting in cell migration and cell cycle progression, in addition to inhibition of apoptosis (Knobbe et al., 2002; Parsons et al., 2008). PTEN mutation and increased Akt/PI3K activity have been correlated with poor prognosis in glioma patients (Ermoian et al., 2002).

In view of the potential contributory roles of antiapoptotic proteins, such as Bcl-2, NFκB, and Akt to glioma apoptosis resistance (Hanahan and Weinberg, 2000, 2011; Knobbe et al., 2002; Omuro et al., 2007; Parsons et al., 2008), we examined the efficacy of ABT-737 and bortezomib in malignant human glioma cell lines as a function of PTEN status and the relationship between inhibition of these targets and apoptosis induction.

Materials and Methods

Cell Lines. The established malignant glioma cell lines U87 and LN229 were obtained from the American Type Culture Collection (Manassas, VA). LN18, LN2308, and LNZ428 were provided by Dr. Nicolas de Tribolet (University of Lausanne, Switzerland). U87 cells were cultured in growth medium composed of minimum essential medium; all other lines were cultured in α-minimal essential medium. All growth media contained 10% fetal calf serum, L-glutamine, 100 IU/ml penicillin, and 100 mg/ml streptomycin (Invitrogen, Carlsbad, CA) supplemented with sodium pyruvate and nonessential amino acids. LN18, LN229, and LNZ428 are wild type for PTEN. However, LNZ308 and U87 are PTEN-deficient glioma cell lines. PTEN status of these glioma cell lines has been characterized elsewhere (Furnari et al., 1997).

Reagents and Antibodies. ABT-737, 3-[4-[4-morpholinyl]pyrido[3',2',4':5,6]pyrimidin-2-yl]pyrimidin-2-ylphosphonic acid (PF-103), and bortezomib were purchased from Chemie Tek (Indianapolis, IN). N-acetyl-L-cysteine (NAC), 2-morpholin-4-yl-8-phenylochromone-4-one (LY294002), and (2S,3S)-trans-epoxysuccinyl-1-leucylamido-3-methylbutylic ethyl ester (E64d) were purchased from EMD Chemicals (Gibbstown, NJ). The protein cross-linker di(butylisuccinimidyipropanone) (DSP) was purchased from Thermo Fisher Scientific (Waltham, MA). Caspase inhibitors (Z-VAD-FMK, Z-ETD-FMK, Z-DEVD-FMK, and Z-LEHD-FMK) were purchased from R&D Systems (Minneapolis, MN). The following antibodies from Cell Signaling Technology (Danvers, MA) were used: Bcl-2, Bcl-xL, Mcl-1, Bim, Bak, Bax, A1/B8.1, Apaf-1, Bcl-w, Bid, cytochrome c, cleaved poly(ADP) ribose polymerase (PARP), cleaved caspase-3, cleaved caspase-8, cleaved caspase-9, total Akt, phospho Akt, PTEN, Smac/DIABLO, and β-actin. Noxa and apoptosis-inducing factor (AIF) were from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA). Monoanodal anti-Bax was from BD Pharmingen (San Diego, CA).

Cell Proliferation and Cytotoxicity Assay. Cells (5 × 10³/well) were plated in 96-well microtiter plates (Costar; Corning Life Sciences, Cambridge, MA) in 100 μl of growth medium, and after over...
night attachment, exposed for 3 days to inhibitors or vehicle (DMSO). After the treatment interval, cells were washed in medium, and the number of viable cells was determined by using a colorimetric cell proliferation assay (CellTiter96 Aqueous Nonradioactive Cell Proliferation Assay; Promega, Madison, WI) as described previously (Jane et al., 2011). Morphological changes in response to inhibitor treatment were evaluated by microscopic inspection and imaging of cells by using an Olympus (Tokyo, Japan) FluoView 1000 microscope. Images were assembled by using Adobe Photoshop CS2 software (Adobe Systems, San Jose, CA).

Clonogenic Growth Assay. The effect of inhibitor treatment on colony-forming ability was assessed by using a clonogenic assay. A total of 250 cells were plated in six-well trays in growth medium, and after overnight attachment, exposed to inhibitors or vehicle for 1 day. Cells were then washed with inhibitor-free medium, grown for 2 weeks under inhibitor-free conditions, and fixed and stained (Hema 3 Manual Staining Systems; Thermo Fisher Scientific). Plates were then scanned, and images were assembled by using Adobe Photoshop CS2 software.

Annexin V Apoptosis Assay. Apoptosis was evaluated by using a fluorescein isothiocyanate (FITC)-conjugated annexin V/propidium iodide (PI) assay kit (Invitrogen) based on annexin V binding to phosphatidylserine exposed on the outer leaflet of the plasma membrane lipid bilayer of cells entering the apoptotic pathway as described previously (Jane et al., 2011). In brief, cells were treated with or without inhibitors for the indicated duration, collected by trypsin-EDTA, pelleted by centrifugation (1000 rpm for 5 min), washed in ice-cold phosphate-buffered saline (PBS), and resuspended in the annexin V-FITC and 1 μg/ml propidium iodide reagent in the dark for 15 min before flow cytometric analysis. Labeling was analyzed by flow cytometry with a FACSCalibur flow cytometer (BD Biosciences, San Jose, CA). A minimum of 20,000 cells per sample was collected.

Subcellular Fractionation. Cells were treated with or without inhibitors, and cytosolic proteins were fractionated as described previously (Premkumar et al., 2011). In brief, cells were resuspended in a lysis buffer containing 0.025% digitonin, 250 mM sucrose, 20 mM EDTA, and 10 mM leupeptin. After 10-min incubation at 4°C, cells were centrifuged (2 min at 13,000g), and the supernatant (cytosolic fraction) was removed and frozen at −80°C for subsequent use.

3′,3′-Dihexyloxacarbocyanine Iodide Labeling and Detection of Mitochondrial Membrane Depolarization. Mitochondrial membrane depolarization was measured as described previously (Jane et al., 2011; Premkumar et al., 2011). In brief, floating cells were collected, and attached cells were trypsinized and resuspended in PBS. Cells were loaded with 50 nM 3′,3′-dihexyloxacarbocyanine iodide (DiOC6; Invitrogen) at 37°C for 15 min. The positively charged DiOC6 accumulates in intact mitochondria, whereas mitochondria with depolarized membranes accumulate less DiOC6. Cells were spun at 3000g, rinsed with PBS twice, and resuspended in 1 ml of PBS. Fluorescence intensity was detected by flow cytometry and analyzed with CellQuest software (BD Biosciences). The percentage of cells with decreased fluorescence was determined.

Western Blotting Analysis. Western blot analysis was performed as described previously (Jane et al., 2011; Premkumar et al., 2011). Equal amounts of protein were separated by SDS-polyacrylamide gel electrophoresis (PAGE) and electrotransferred onto a nylon membrane (Invitrogen). Nonspecific antibody binding was blocked by incubation of the blots with 4% bovine serum albumin in Tris-buffered saline/Tween 20 (0.1%) for 1 h at room temperature. The blots were then probed with appropriate dilutions of primary antibodies as described previously (Jane et al., 2011). Where indicated, the blots were stripped and reprobed with antibodies against β-actin to ensure equal loading and transfer of proteins.

In Vitro Cross-Linking and Analysis of Bax Oligomerization. Cytosolic and membrane fractions were prepared by selective plasma membrane permeabilization with 0.05% digitonin, followed by membrane solubilization with 1% CHAPS as described elsewhere (Mikhailov et al., 2001). In brief, control and experimental cells in dishes were treated with 0.05% digitonin in isotonic buffer (10 mM HEPES, 150 mM NaCl, 1.5 mM MgCl2, and 1 mM EGTA, pH 7.4) containing protease inhibitors (1 mM 4-(2-aminoethyl) benzenesulfonyl fluoride hydrochloride, 0.8 mM aprotinin, 50 mM bestatin, 15 mM E64d, 20 mM leupeptin, and 10 mM pepstatin A) for 1 to 2 min at room temperature. The permeabilized cells were shifted to 4°C, scraped with a rubber policeman, and collected into centrifuge tubes. The supernatants (digitonin-extracted cytosolic fraction) were routinely collected after centrifugation at 15,000g for 10 min. After centrifugation, the pellet was washed with isotonic buffer and further extracted with ice-cold detergent (1% CHAPS) in isotonic buffer containing protease inhibitors for 60 min at 4°C to release membrane- and organelle-bound proteins including mitochondrial cytochrome c. CHAPS-soluble (membrane fraction) were collected by high-speed (15,000g) centrifugation for 10 min. The protein cross-linker DSP was dissolved in DMSO and prepared just before use. Equal amounts of CHAPS-solubilized membrane fraction protein were incubated with 1 mM DSP for 45 min at room temperature and subsequently quenched by adding 20 mM Tris-HCl, pH 7.4. Proteins were resolved by nonreducing SDS-PAGE, and immunoblots were analyzed as described above.

Measurement of Active Bax Staining. After treatment, cells were detached and fixed in 3.7% prewarmed formaldehyde (Sigma, St. Louis, MO) (15 min, room temperature), and then washed three times (5 min) with PBS buffer. Cells were permeabilized with 0.1% Triton X-100/PBS buffer for 15 min at room temperature before being incubated with blocking solution for 2 h (0.3% bovine serum albumin and 1% goat serum in PBS). Primary antibody was added in the same buffer and incubated overnight at 4°C. Anti-active-human-Bax antibody (6A7; BD Pharmingen) was used at a 1:100 dilution. Fluorescein isothiocyanate-conjugated secondary antibody (Invitrogen) was used at a 1:200 dilution (60 min in the dark, room temperature). Stained cells were analyzed by flow cytometry. The average percentage increase in Bax-activated cells was calculated over the DMSO controls.

Adenovirus Infection. PTEN wild-type adenovirus (Ad-PTEN wild type) and Ad-CMV were kindly provided by Dr. Craig Henke (University of Minnesota, Minneapolis, MN) and Dr. Christopher Kontos (Duke University Medical Center, Durham, NC), respectively. Ad-Akt [dominant negative (DN)] was purchased from Vector Biolabs (Philadelphia, PA). Glioma cells were infected with adenovirus vectors at the indicated multiplicity of infection (MOI) for 48 h at 37°C. The medium was changed and treated with inhibitors for the indicated duration. Cells were processed for Western blot or annexin V apoptosis analysis as described above.

Transient Transfection or Stable Cell Line Generation. Empty vector pcDNA3 was from Dr. Michael Greenberg (Harvard Medical School, Boston, MA). The expression vector pcDNA3-Bcl-2 was obtained from Dr. Stanley Korsmeyer (Dana Farber Cancer Institute, Boston, MA). pcDNA3-Myr-HA-Akt1 was obtained from Dr. William Sellers (Dana Farber Cancer Institute). Glioma cell lines were plated in six-well plates, maintained in complete media, and kept in 37°C in a humidified 5% CO2 incubator. Transfection was performed at 60 to 70% confluence by using FuGENE 6 (Roche Diagnostics, Indianapolis, IN) according to the manufacturer’s recommendations. The total amount of transfected DNA was maintained at 1 μg. After a 48-h transient transfection period, cells were treated with or without inhibitors for an additional 24 h. Stable cell lines were generated after selection with G418 (250 μg/ml) following the method described by the manufacturer (Invitrogen). Cells were processed for Western blot or annexin V apoptosis analysis as described above. Control cells received equal amounts of DMSO.

Statistical Analysis. Unless otherwise stated, data are expressed as mean ± S.D. The significance of differences between experimental conditions was determined by using a two-tailed Student’s t test. Differences were considered significant at p < 0.05.
Results

ABT-737 as a Monotherapy Is Ineffective in Human Glioma Cells. ABT-737 has monotherapeutic toxicity against leukemia, lymphoma, and other malignancies (Konopleva et al., 2006; Tahir et al., 2007; Trudel et al., 2007; Bodet et al., 2011; Song et al., 2011). Established cell lines or primary cells from patients with chronic lymphocytic leukemia (Del Gaizo Moore et al., 2007), acute lymphocytic leukemia (Del Gaizo Moore et al., 2008; High et al., 2010), and B lymphoma (Vogler et al., 2008) have been shown to be extremely sensitive to ABT-737. In this article, we examined the effect of ABT-737 on malignant human glioma cell lines. Cells were treated with increasing concentrations of ABT-737, and cell proliferation was assessed by MTS assay after 24, 48, and 72 h. ABT-737 alone produced minimal effects on cellular proliferation. We observed that glioma cells are differentially sensitive to ABT-737; we found moderately sensitive (72 h, IC50 ~10–15 μM; LN18, LN229, and LNZ428) and resistant (72 h, IC50 >50 μM; U87 and LNZ308) glioma cell lines (Fig. 1A). Microscopic analysis after 24 h revealed that ABT-737 (10 μM) caused cell rounding, reduced cell size, and blebbing in the ABT-737-sensitive but not in the resistant cell lines (data not shown). We further examined whether ABT-737-treated cells exhibited delayed onset cell death by assessing colony-forming activity. Cells were incubated with either medium or ABT-737 (0–10 μM) for 24 h. After 1 day, inhibitor was removed, and then cells were cultured in inhibitor-free medium for 14 additional days. As shown in Fig. 1B, no significant difference in colony-forming ability was observed between untreated and ABT-737-treated cells, suggesting the limited independent activity of ABT-737 in these tumors when administered within the clinically achievable range.

Overexpression of Bcl-2 in Glioma Does Not Result in Enhanced Protection to ABT-737. Recent studies have shown that high Bcl-2 or low Mcl-1 expression levels correlate with increased sensitivity to ABT-737 in different cancers (van Delft et al., 2006; Lin et al., 2007; Tahir et al., 2007). Because ABT-737 targets the antiapoptotic Bcl-2 family proteins (Bcl-2, Bcl-xL, and Bcl-w), thereby sequestering proapoptotic BH3 domain proteins, promoting Bax and Bak oligomerization, and ultimately programming the cell death of malignant cells (Oltersdorf et al., 2005), we studied the expression profile of Bcl-2 family members. As shown in Fig. 2A, Bcl-2 was expressed at variable levels with the highest levels detected in U87 and LNZ308 cells (ABT-737-resistant cell lines), and the lowest levels were in LN18, LN229, and LNZ428 cells (moderately sensitive to ABT-737). However, all cell lines ubiquitously expressed Bcl-xL, Bcl-w, and Mcl-1. For proapoptotic proteins, Bax, Bak, Bid, and Noxa was expressed ubiquitously at similar levels in all cell lines tested.

To determine the role of Bcl-2 in ABT-737-induced apoptosis, ABT-737-sensitive LN229 cells were stably transfected with the human Bcl-2 cDNA or vector alone (pcDNA3). G418-resistant clones found to overexpress Bcl-2 proteins were selected and used for subsequent experiments (clones 10 and 11). Overexpression of Bcl-2 did not result in changes in expression of other Bcl-2 family members (Fig. 2B). Bcl-2-overexpressing cells were incubated with increasing concentrations of TRAIL or ABT-737, and cell proliferation (after 72 h) was assessed by MTS cell proliferation assay. As shown in Fig. 2C, overexpression of Bcl-2 almost completely inhibited TRAIL-induced cell killing (Fig. 2C, top); whereas there was no indication that enhanced Bcl-2 expression in turn influenced glioma cells response to ABT-737 (Fig. 2C, bottom). Annexin V/PI dye binding assay revealed that treatment with TRAIL resulted in 78% cell death in LN229 cells expressing control vector compared with 20% cell death in LN229 cells stably expressing Bcl-2 (Fig. 2D). However, there was no indication that enhanced Bcl-2 expression in turn protected cells from ABT-737 toxicity, suggesting that high levels of Bcl-2 expression did not play a key role in mediating the resistance to ABT-737 in malignant human glioma cell lines.

Cotreatment of Bortezomib and ABT-737 Induces Apoptotic Cell Death. In our recent studies, we demonstrated that bortezomib exhibited significant activity against proliferation in glioma cells and sensitized highly resistant glioma cells to TRAIL (Jane et al., 2011) or HDACI-induced cytotoxicity (Premkumar et al., 2011). Because several members of the Bcl-2 family (Yu et al., 2008; Premkumar et al., 2011), Akt (Yu et al., 2006) and NF-κB (Jane et al., 2011), are known targets of bortezomib in glioma, we investigated the combination of bortezomib and ABT-737 to assess sensitivity in vitro. The combination of ABT-737 and bortezomib strongly induced apoptosis and activated caspase-3 and PARP, and to a lesser extent, caspase-8 and caspase-9 (data not shown), relative to untreated control cells in ABT-737-

Additional information and data from the figures and tables are provided in the supplementary materials.
Bortezomib Sensitizes Glioma Cells to ABT-737

sensitive LN229 (Fig. 3A) and LN18 (Fig. 3B) cell lines. In contrast, cotreatment of bortezomib and ABT-737 failed to induce apoptosis in U87 (Fig. 3C) and LNZ308 (Fig. 3D) cell lines. Annexin V/PI apoptosis analysis further demonstrated that U87 and LNZ308 cells showed no sensitivity to ABT-737 (0–10 μM) and minimal or no response in combination with bortezomib (10 μM ABT-737 + 5 nM bortezomib) (data not shown).

To demonstrate that apoptosis induced by ABT-737 and bortezomib is caspase-dependent; we pretreated cells with Z-VAD-FMK and observed the combination of bortezomib and ABT-737-induced caspase-3 and PARP activation. As shown in Fig. 3E, the addition of the broad-range caspase inhibitor Z-VDV-FLMK completely abolished ABT-737 + bortezomib-induced PARP activation in the LN18 and LN229 cell lines. Annexin V apoptosis assay (Fig. 3E) clearly demonstrated that ABT + bortezomib-induced cell death was inhibited by Z-VDV-FLMK. Taken together, these experiments demonstrate that the combination of ABT-737 and bortezomib induces apoptosis in a subset of malignant human glioma cell lines, although others remain resistant.
Fig. 3. Cotreatment of bortezomib and ABT-737 induces apoptotic cell death. A to D, LN18 (A), LN229 (B), U87 (C), and LNZ308 (D) cells were seeded at 60% confluence, allowed to attach overnight, and treated with 5 nM bortezomib (B), 2.5 μM ABT-737 (A), or a combination of both (B + A). Control cells received an equivalent amount of DMSO. Apoptosis was assessed by annexin V-FITC and PI staining and FACS analysis as described under Materials and Methods. The representative histogram (top) and the bar chart (bottom left; indicating apoptotic cells) show data from three independent experiments. Asterisks indicate significant differences in relation to single agent alone (**, p < 0.005). In parallel, cell extracts were prepared, and equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies (bottom right). β-Actin served as loading control.

E, LN18 and LN229 cells were pretreated with 25 μM Z-VAD-FMK (pan caspase inhibitor) for 2 h followed by the combination of bortezomib (5 nM) plus ABT-737 (2.5 μM; B + A) for 24 h. Control cells received an equivalent amount of DMSO. Apoptosis (top; representative annexin V binding histogram; bottom left, bar chart representing three independent experiments) was analyzed by flow cytometry as described under Materials and Methods. **, p < 0.005, values considered statistically significant. In parallel, cell extracts were prepared, and equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies (bottom right). β-Actin served as loading control.
The High Levels of Akt in PTEN-Deficient U87 and LNZ308 Cell Lines Mediate the Reduced Response to ABT-737 and Bortezomib-Induced Apoptosis. Because Akt is a central regulator of many intracellular processes implicated in glioma tumor progression and PTEN, the negative regulator of Akt, is functionally inactivated in a significant proportion of advanced human gliomas (Chakravarti et al., 2004; Parsons et al., 2008), we explored whether increased Akt activity may be involved in ABT-737 + bortezomib resistance. To test the hypothesis that response to ABT-737 and bortezomib is associated with PTEN status, first we explored the relationship between PTEN and the activation status of Akt by Western blot analysis using phospho-Active-Akt antibody, which recognizes the phosphorylation of Ser473 of Akt, and PTEN antibody, respectively. Western blot analysis revealed that LN18, LN229, and LNZ428 (PTEN-proficient) cells express PTEN protein, whereas PTEN-mutated U87 and LNZ308 cells do not express this protein (Fig. 4A). PTEN-expressing cells possess lower levels of activated (phosphorylated) Akt compared with PTEN-deficient cells. No change in total Akt and β-actin levels was observed (Fig. 4A).

To test whether Akt inhibition restores bortezomib and ABT-737 sensitivity, we used pharmacologic and genetic tools to perturb these pathways. PTEN-deficient U87 and LNZ308 cells were infected with adenovirus-expressing empty vector (Ad-CMV) or Ad-PTEN. As shown in Fig. 4B, the initial adenoviral infection and immunoblotting experiments revealed a dose-dependent increase of PTEN activation in glioma cells without altering total Akt protein level. As expected, expression of wild-type PTEN efficiently led to the dephosphorylation of Akt/PKB kinase (Fig. 4B), a downstream target of the PI3K-Akt pathway that is dephosphorylated and inactivated by PTEN (Stambolic et al., 1998), indicating that the increased Akt expression in the PTEN-mutated cell lines directly resulted from reduced PTEN expression and restoration of PTEN expression reversed this effect.

To determine whether directly inhibiting Akt could restore bortezomib and ABT-737 sensitivity, U87 cells were infected with adenovirus-expressing dominant negative Akt (Ad-Akt-DN) or empty vector (Ad-CMV). Forty eight hours after infection, cells were incubated with or without bortezomib and ABT-737 for an additional 24 h, and apoptosis was determined by fluorescence-activated cell sorting (FACS) and Western blot analysis. Cotreatment with bortezomib and ABT-737 in cells infected with DN Akt resulted in a significant increase in apoptosis (Fig. 4C, top). Akt (DN)-infected U87 cells were more sensitive to bortezomib + ABT-737 (55% apoptosis compared with 22% in vector control; Fig. 4C, bottom left). This was further confirmed by Western blot analysis (combination of bortezomib and ABT-737 resulted in pronounced activation of PARP; Fig. 4C, bottom right), suggesting that the inhibition of the PI3K/Akt signaling pathway was critical to the combined effect of bortezomib and ABT-737 in PTEN-deficient glioma cell lines. A similar result was obtained when cells were infected with PTEN adenovirus (data not shown). To validate these results, U87 and LNZ308 cells were pretreated with the pharmacological inhibitor of PI3K/Akt, LY294002, or PI-103 in complete medium 2 h before treatment with bortezomib + ABT-737 for 24 h. Cells were processed for annexin V apoptosis by FACS analysis. Figure 4D revealed that pretreatment with LY-294002 or PI-103 resulted in 40 and 80% cell death compared with ABT-737 + bortezomib resulting in 15% cell death in U87 cells (Fig. 4D). These data clearly suggest that elevated expression of phosphorylated Akt caused by the loss of PTEN function may play an important role in ABT-737 and bortezomib resistance seen in malignant human glioma cell lines.

Cotreatment of ABT-737 and Bortezomib Potentiates Cytochrome c Release from Mitochondria and Induces Mitochondrial Transmembrane Potential Decrease. Because bortezomib induces mitochondrial membrane potential (ΔΨm) dissipation as a mechanism for promoting apoptosis (Jane et al., 2011; Premkumar et al., 2011), and mitochondrial changes are necessary for the activation of downstream caspases (Nencioni et al., 2005), we compared the effect of bortezomib and ABT-737 on ΔΨm in PTEN-intact (LN18 and LN229) and PTEN-deficient (U87 and LNZ308) cell lines by using DiOC6 (Petit et al., 1990). The mitochondrial uncoupler carbonylcyanide m-chlorophenylhydrazone (CCCP) was used as a positive control for ΔΨm disruption. As shown in Fig. 5A, ABT-737 treatment (0–2.5 μM for 24 h) had no effect on ΔΨm as measured by flow cytometry. However, treatment of 5.0 μM ABT-737 significantly increased the LN229 (11%) and LN18 (19%) cell population with low ΔΨm (Fig. 5A). However, no significant change in ΔΨm (Fig. 5B) was seen in the U87 or LNZ308 cell lines. Then we investigated the combined effect of bortezomib and ABT-737. The number of LN18 and LN229 cells with ΔΨm increased to 60 and 72%, respectively (from ~ 7% in single-agent treatment) after ABT-737 and bortezomib treatment (Fig. 5C). Because disruption of ΔΨm may cause the release of cytochrome c and other mitochondrial apoptogenic proteins, we examined the release of cytochrome c, Smac/DIABLO, and apoptosis-inducing factor to the cytosol after inhibitor treatment, alone or in combination in LN229 cells. As shown in Fig. 5D, the signal of cytochrome c and Smac/DIABLO was barely detectable in the cytosol when the cells were incubated with bortezomib or ABT-737 alone, but was clearly detected with the combination of bortezomib and ABT-737. Under the same conditions, we also detected the release of apoptosis-inducing factor (AIF), another apoptotic regulator, with a similar pattern to that of cytochrome c release. However, the percentage of cells with low ΔΨm increased modestly in U87 and LNZ308 cells (26 and 13% respectively) after ABT-737 + bortezomib treatment (Fig. 5E).

To validate the above findings that the elevated expression of PI3K/Akt signaling inhibits ABT-737- and bortezomib-induced apoptosis by maintaining the integrity of mitochondria in PTEN-deficient cell lines, we examined whether the inhibition of PI3K/Akt signals would alter mitochondrial transmembrane potential. U87 and LNZ308 cells were pretreated with the Akt inhibitor PI-103 2 h before bortezomib + ABT-737 treatment for 24 h. As shown in Fig. 5F, treatment of U87 and LNZ308 cell lines with PI-103 led to a significant loss of ΔΨm as indicated by an increase in the percentage of cells showing ΔΨm from 26% in ABT-737 + bortezomib-treated U87 cells to 71% in cells pretreated with PI-103, suggesting that the PI3K/Akt kinase may lie upstream of mitochondria.

To determine whether the loss of mitochondrial potential in LN229 cells was a direct result of caspase activation, we examined the effect of Z-VAD-FMK on ABT-737- and bort-
Fig. 4. The high levels of Akt in PTEN-deficient U87 and LNZ308 cell line mediate the reduced response to ABT-737 and bortezomib-induced apoptosis. A, five established human glioma cells were seeded at 60% confluence and allowed to attach overnight. Cell extracts were prepared, and equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies. β-Actin served as loading control. B, logarithmically growing LN18, LN229, LN2428, U87, and LNZ308 cells were infected with Ad-PTEN at the indicated MOI or empty vector (Ad-CMV, 200 MOI per cell). Forty eight hours after infection, cells were lysed, and equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies. C, U87 cells were infected with 50 MOI of empty vector (Ad-CMV) or Ad-Akt-dominant negative (Ad-Akt DN). Forty eight hours after infection, cells were incubated in the presence of bortezomib (5 nM) and ABT-737 (indicated concentration) for 24 h. Control cells received DMSO (vehicle). At the end of the incubation period, the viable cell numbers were determined by flow cytometric analysis (top). In the histogram (bottom left), the mean number of apoptotic cells acquired from three independent experiments is shown. B, 5 nM bortezomib; A, 2.5 μM ABT-737; B + A, combination of bortezomib (5 nM) and ABT-737 (2.5 μM). The values represent the mean ± S.D., **p < 0.005 values considered statistically significant. In parallel experiments (bottom right) cell extracts were prepared, and equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies. B, 5 nM bortezomib; A, 2.5 μM ABT-737; B + A, combination of bortezomib (5 nM) and ABT-737 (2.5 μM). β-Actin served as loading control. D, U87 and LNZ308 cells were seeded at 60% confluence and allowed to attach overnight. The next day, cells were pretreated with 25 μM LY294002 or 5 μM PI-103 (PI3K/ Akt inhibitor) for 2 h followed by the inhibitors bortezomib (5 nM) or ABT-737 (2.5 μM) or a combination of both (B + A) for 24 h. Control cells received DMSO (vehicle). At the end of the incubation period, the viable cell numbers were determined by flow cytometric analysis (top left). The bar chart (top right) represents the mean number of apoptotic cells acquired from three independent experiments. The values represent the mean ± S.D., **p < 0.005 values considered statistically significant. In parallel experiments (bottom) cell extracts were prepared, and equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies. B, 5 nM bortezomib; A, 2.5 μM ABT-737; B + A, combination of bortezomib (5 nM) and ABT-737 (2.5 μM). β-Actin served as loading control.
Bortezomib Sensitizes Glioma Cells to ABT-737

Mean number of cells acquired from three independent experiments. Asterisks indicate significant differences in relation to control (\(**\), \(p < 0.005\)). C, LN18 and LN229 cells were treated with 1 or 2.5 \(\mu M\) ABT-737 in combination with or without bortezomib (5 nM) for 24 h. Control cells received equivalent amounts of DMSO. Loss of mitochondrial membrane potential was determined by DiOC6 staining and flow cytometry as described under Materials and Methods. Equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies. E, U87 and LNZ308 cells were treated with 2.5 \(\mu M\) ABT-737 in combination with or without bortezomib (5 nM) for 24 h. Control cells received equivalent amounts of DMSO. Loss of mitochondrial membrane potential was determined by DiOC6 staining and flow cytometry as described under Materials and Methods. Histogram (top) and the bar chart (bottom) represent the mean number of \(\Delta\Psi_m\) cells acquired from three independent experiments. Asterisks indicate significant differences in relation to single agent alone (\(**\), \(p < 0.005\)). D, LN229 cells were incubated with inhibitors at the indicated concentrations of ABT-737 with or without bortezomib (5 nM) for 24 h. Control cells received equal amounts of DMSO. Cytosolic extracts and the digitonin-insoluble pellets were prepared as described under Materials and Methods. Equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies. E, U87 and LNZ308 cells were treated with 2.5 \(\mu M\) ABT-737 in combination with or without bortezomib (5 nM) for 24 h. Control cells received equivalent amounts of DMSO. Loss of mitochondrial membrane potential was determined by DiOC6 staining and flow cytometry as described under Materials and Methods. Histogram (top) and the bar chart (bottom) represent the mean number of \(\Delta\Psi_m\) cells acquired from three independent experiments. Asterisks indicate significant differences in relation to single agent alone (\(**\), \(p < 0.005\)). F, U87 and LNZ308 cells were seeded at 60% confluence and allowed to attach overnight. The next day, cells were pretreated with 5 \(\mu M\) PI-103 (PI3K/Akt inhibitor) for 2 h followed by the inhibitors bortezomib (5 nM) or ABT-737 (2.5 \(\mu M\)), or the combination of both (B + A) for 24 h. Control cells received equivalent amounts of DMSO. Loss of mitochondrial membrane potential was determined by DiOC6 staining and flow cytometry as described under Materials and Methods. Histogram (top) and the bar chart (bottom) represent the mean number of \(\Delta\Psi_m\) cells acquired from three independent experiments. Asterisks indicate significant differences in relation to single agent alone (\(**\), \(p < 0.005\)). G, LN18 and LN229 cells were pretreated with 25 \(\mu M\) Z-VAD-FMK (Z, pan caspase inhibitor) or 5 mM NAC (N, ROS scavenger) for 2 h followed by the combination of bortezomib (5 nM) and ABT-737 (2.5 \(\mu M\), B + A) for 24 h. Control cells received equivalent amounts of DMSO. Loss of mitochondrial membrane potential was determined by DiOC6 staining and flow cytometry as described under Materials and Methods. Histogram (top) and the bar chart (bottom) represent the mean number of \(\Delta\Psi_m\) cells acquired from three independent experiments. Caspase inhibitor and ROS scavenger partially inhibit bortezomib + ABT-737-induced loss of mitochondrial membrane potential (the values represent the mean ± S.D.; \(**\), \(p < 0.005\)). H, vector control (LN229) or Bcl-2 stably expressing transfectants (LN229-Bcl-2) cells were seeded at 60% confluence and allowed to attach overnight. Cells were treated with 2.5 \(\mu M\) ABT-737 in combination with or without bortezomib (5 nM) for 24 h. Control cells received equivalent amounts of DMSO. Loss of mitochondrial membrane potential was determined by DiOC6 staining and flow cytometry as described under Materials and Methods. Histogram (top) and the bar chart (bottom) represent the mean number of \(\Delta\Psi_m\) cells acquired from three independent experiments. The values represent the mean ± S.D. NS, not significant.
ezomib-induced dissipation of Δψm. Preincubation of LN229 cells with the pan caspase inhibitor (Z-VAD-FMK) or the ROS scavenger (NAC) prevented the loss of Δψm (reduced to 23 or 47%, respectively), suggesting that cotreatment with bortezomib + ABT-737 promoted Δψm, leading to apoptotic death (Fig. 5G) via the caspase-dependent pathway. Then we examined whether overexpression of Bcl-2 protected LN229 cells from the loss of Δψm. As shown in Fig. 5H, we found that there was no significant change in Δψm from the stably transfected cells and the vector-transfected cells. Taken together, these data suggest that the phosphorylation level of Akt, a key antiapoptotic protein (and PTEN status), plays an important role in maintaining mitochondrial membrane integrity, thus determining the sensitivity of glioma cells to ABT-737 and bortezomib treatment.

Activation of Bid and Bax Contributes to Bortezomib-Mediated Sensitization to ABT-737. Bcl-2 family member Bid, a substrate of caspase-8, can move to the mitochondrial membrane and contributes to the opening of the permeability transition pore when Bid is cleaved by caspase (Zamzami et al., 2000). Because a decrease in Δψm and release of cytochrome c from the mitochondria have been shown to be initiated by the translocation of a 15-kDa truncated Bid (tBid) from the cytosol to the mitochondria (Yin, 2000), we investigated the effect of bortezomib and ABT-737 on this process in glioma cell lines. As shown in Fig. 6A, treatments with these inhibitors individually caused no effect on Bid truncation. However, the combination of ABT-737 with bortezomib treatment significantly increased the cleaved forms of Bid in LN18, LN229, and LNZ428 (PTEN-intact) cell lines (Fig. 6A). In contrast, no Bid cleavage was evident in U87 and LNZ308 (PTEN-deficient) cell lines (Fig. 6A). For example, U87 and LNZ308 cells showed no sensitivity to ABT-737 (0–10 μM) and no response (appearance of tBid fragment) in combination with bortezomib (10 μM ABT-737 + 5 nM bortezomib).

Because caspase-8 (Gross et al., 1999), caspase-3 (Slee et al., 2000), and calpain (Mandic et al., 2002) are the best characterized proteases responsible for the cleavage of Bid, we incubated LN229 cells with caspase-8 (Z-IETD-FMK), caspase-3 (Z-DEVD-FMK), pan-caspase (Z-VAD-FMK), or calpain (E64d) inhibitors at 25 μM for 2 h before the addition of bortezomib and ABT-737. As shown in Fig. 6B, pretreatment of cells with caspase-8, caspase-3, and pan caspase inhibitors completely prevented inhibitor-induced generation of tBid, suggesting that caspase-8 and caspase-3 are indispensable for bortezomib- and ABT-737-induced cleavage of Bid to tBid, accompanied by reduction in the levels of active PARP. However, blockade of calpain activity with E64d had no effect on the proteolytic processing of Bid and PARP cleavage after inhibitor treatment.

Because tBid is thought to occur via its stimulating effect on the conformational change of Bax, leading to trigger the release of cytochrome c (Espositi, 2002), thus facilitating formation of the Bax/Bak complex (Tagscherer et al., 2008) that initiates mitochondrial membrane permeabilization and apoptosis (Desagher et al., 1999), we examined the effect of ABT-737 and bortezomib on Bax activation. Cells were treated with or without bortezomib and ABT-737 for 24 h. Bax activation is a highly regulated, multistep process involving mitochondrial translocation and oligomerization, and this process ultimately leads to mitochondrial dysfunction and apoptosis (Annis et al., 2005). To examine the effect of bortezomib and ABT-737, we analyzed activity-related conformational changes of Bax by flow cytometric analysis with antibodies recognizing N-terminal epitopes of Bax (anti-bax, 6A7). When LN229 cells were exposed to ABT-737 (1–5 μM) alone, a clear dose-dependent (15.8% in cells exposed to 5 μM) increase in Bax conformational change was observed (Fig. 6C). On the other hand, bortezomib (5 nM) alone minimally induced Bax conformational change. It is noteworthy that cells coexposed to bortezomib and ABT-737 displayed a further increase in Bax conformational change compared with cells treated with ABT-737 alone (Fig. 6D). Parallel studies were then done in ABT-737-resistant U87 cells to assess Bax conformational change. In contrast to results involving LN229, ABT-737 by itself had no effect on Bax activation (3.21% in cells exposed to 5 μM; Fig. 6C), whereas bortezomib + ABT-737 modestly induced Bax activation (approximately 8%, Fig. 6D). Then we examined whether inhibition of PI3K/Akt signals would alter Bax activation in U87 cells. Cells were pretreated with the Akt inhibitor PI-103 or LY294002 2 h before bortezomib + ABT-737 treatment for 24 h. For example, as shown in Fig. 6E, treatment of U87 cells with Akt inhibitor led to a significant increase in Bax activation (pretreatment with PI-103 led to 23.9% and LY294002 led to 17.7% from 8.25%), suggesting that that PI3K/Akt kinase may play a vital role in Bax activation.

Upon the induction of apoptosis, Bax migrates to the mitochondrial, where it is integrated into the outer membrane as a monomer. Bax monomers then oligomerize and may form large pores in the outer mitochondrial membrane (Annis et al., 2005). Because cleaved Bid migrates to mitochondria where it induces permeabilization of the outer mitochondrial membrane that depends on the proapoptotic proteins Bax and/or Bax oligomerization (Desagher et al., 1999; Korsmeyer et al., 2000; Billen et al., 2008), we sought to determine whether bortezomib and ABT-737 might cause Bax oligomerization in PTEN-intact LN229 cells. Membrane fractionation was performed followed by chemical cross-linking with disuccinimidyl suberate as described under Materials and Methods. Western blot analysis of cross-linked proteins showed that Bax oligomerized into dimers and higher in multiples of ~20-kDa monomers (Fig. 6F, left), suggesting that these represented newly formed complexes of Bax.

Then we tested the involvement of the PI3K/Akt pathways on Bax activation. PTEN-deficient U87 cells were pretreated with PI-103 (10 μM) for 2 h before challenging them with ABT-737 and bortezomib for 24 h. The combination of bortezomib + ABT-737 induced a minimal activation of Bax oligomerization. As expected, pretreatment with PI-103 evoked robust Bax oligomerization (Fig. 6F, right) and generation of tBid fragments (Fig. 6G). We next tried to determine whether overexpression of a constitutively active (myr-isolated) Akt1 could protect PTEN-intact LN229 cells from bortezomib + ABT-737-induced apoptosis. Cells were transfected with either the empty vector or the Myr.Akt 1 construct, and apoptosis was assessed by annexin V FACE. As shown in Fig. 6H, cotreatment of ABT-737 and bortezomib induced significant levels of apoptosis in vector-transfected LN229 cells (~68%). However, the apoptotic potential of ABT-737 + bortezomib was reduced to 50% in cells transfected with Myr.Akt 1, strongly suggesting the involvement of the Akt pathway.
Fig. 6. Activation of Bid and Bax contributes to bortezomib-mediated sensitization to ABT-737. A, LN18, LN229, LNZ428, U87, and LNZ308 cells were seeded at 60% confluence, allowed to attach overnight, and treated with 5 nM bortezomib (B) or ABT-737 (indicated concentrations) or a combination of both. Control cells received equivalent amount of DMSO. Cell extracts were prepared, and equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies. β-Actin served as loading control.

B, LN229 cells were pretreated with inhibitors of either caspase-8 (Z-IETD-FMK), caspase-3 (Z-DEVD-FMK), pan-caspase (Z-VAD-FMK), or calpain (E64d) at 25 μM for 2 h before the addition of bortezomib + ABT-737. Cell extracts were prepared, and equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies. β-Actin served as loading control. C, Bax conformational changes in LN229 or U87 cells treated with the indicated concentrations of ABT-737 are presented. After treatment, cells were fixed with formaldehyde and then incubated with 6A7 monoclonal anti-Bax antibody. After incubation with FITC-conjugated secondary antibody for 2 h, the signals of activated conformation of Bax proteins were measured by flow cytometry (representative histograms, left; bar chart, right). Data are representative of three independent experiments. D, LN229 and U87 cells were treated with 2.5 μM ABT-737 in combination with or without bortezomib (5 nM) for 24 h. Control cells received equivalent amounts of DMSO. Bax conformational changes were measured as described under Materials and Methods by flow cytometry (representative histogram, left; bar chart, right). Data are representative of three independent experiments. E, U87 cells were pretreated with 25 μM LY294002 (LY3B) or 5 μM PI-103 (PI3B) for 2 h before the addition of bortezomib + ABT-737 (B + A). Control cells received equivalent amounts of DMSO. Bax conformational changes were measured as described under Materials and Methods by flow cytometry (representative histogram, left; bar chart, right). Data are representative of three independent experiments. F, LN229 cells (left) were treated with ABT-737 (indicated concentrations) in combination with or without bortezomib (5 nM) for 24 h. Control cells received equivalent amounts of DMSO. U87 cells (right) were pretreated with 5 μM PI-103 (PI3B) or 2.5 μM ABT-737 (A) for 2 h before the addition of 5 nM bortezomib (B + A). Control cells received equivalent amounts of DMSO. Membrane fractions were obtained as described under Materials and Methods, and proportional amounts corresponding to total protein were analyzed for Bax oligomerization by Western blotting under nonreducing conditions. Slow-moving Bax oligomers in DSP cross-linked cells were derived from Bax monomers, and the molecular masses of oligomers containing Bax were calculated by plotting their migrations against migrations of molecular mass standards. G, U87 cells were pretreated with 5 μM PI-103 (PI3B) for 2 h before the addition of both bortezomib (5 nM) and 2.5 μM ABT-737 (B + A). Control cells received equivalent amounts of DMSO. Cell extracts were prepared, and equal amounts of protein were separated by SDS-PAGE and subjected to Western blotting analysis with the indicated antibodies. β-Actin served as loading control. H, LN229 cells were transiently transfected with pcDNA 3 (vector) or Myr. Akt1. Forty eight hours after transfection, cells were treated with bortezomib (B, 5 nM), ABT-737 (A, 2.5 μM), or a combination of both (B + A). Apoptosis was determined by FACS analysis. Data represent mean ± S.D of three independent experiments carried out in triplicate. *, p < 0.001.
Discussion

Multiple factors contribute to the development of drug resistance of cancer cells, including reduction of intracellular drug accumulation, increase in DNA damage repair, constitutive activation of PI3K/Akt signaling, activation of the Ras and mitogen-activated protein kinase pathways, and dysfunction of the tumor suppressor genes. In this article, we have shown for the first time that elevated expression of Akt is a crucial mediator of apoptosis sensitivity in response to ABT-737 and bortezomib, inhibitors of Bel-2 and NF-κB, respectively, in glioma cells. This calls attention to the need to target multiple apoptosis-promoting mediators in these treatment-resistant tumors. Our study showed that, unlike hematologic malignancies (Konopleva et al., 2006; Vogler et al., 2008; High et al., 2010; Bodet et al., 2011), glioma cells are relatively resistant to ABT-737 in that a relatively high dose of ABT-737, well above the clinically achievable range, was required to suppress cell proliferation and induce apoptosis in vitro, even among the more sensitive cell lines. Our analysis of a panel of glioma cell lines showed no correlation between Bel-2 family protein expression level and response to ABT-737. This lack of correlation of sensitivity with Mcl-1 or other Bel-2 family protein expression has also been shown in other cancers (Hauck et al., 2009). We demonstrated that enforced Bel-2 overexpression does not influence ABT-737-induced inhibition of cell proliferation or induction of apoptosis in glioma cell lines, which are already fairly resistant to this agent, but does induce resistance to TRAIL-mediated apoptosis. These findings are consistent with data from others who showed that Bel-2, when ectopically overexpressed, could not block ABT-737-dependent apoptosis of small-cell lung cancer cells (Hauck et al., 2009).

Recently, we have shown that the proteasome inhibitor bortezomib synergizes with TRAIL (Jane et al., 2011) and HDACI (Premkumar et al., 2011) in glioma cells. Bortezomib treatment causes multiple changes in the cell, including inhibition of NF-κB, a transcription factor that is activated and contributes to the survival of glioma cells. In addition, bortezomib induces the generation of ROS and mitochondrial membrane dysfunction and alters the balance between proapoptotic and antiapoptotic Bel-2 family members. Hence, we sought to determine whether direct targeting of Bel-xL and Bel-2 using a highly specific small-molecule inhibitor (ABT-737) would result in synergism with bortezomib, given that NF-κB and Bel family members were noted in our previous studies to be key apoptosis-resistance nodes in glioma cells. Indeed, the combination of ABT-737 with bortezomib resulted in synergistic induction of glioma cell death, as measured by annexin V, clonogenic survival, and Western blot analysis in glioma cell lines with intact PTEN expression. The combination of drugs strongly induced mitochondrial membrane depolarization, as shown by flow cytometry with DiOC6 dye and subsequent potent induction of apoptosis. The combination of bortezomib and ABT-737 induced the loss of Δψm and the release of cytochrome c to the cytoplasm, indicating that this drug combination acts via the mitochondrial death pathway. In addition, the observation that caspase-8 was activated by these inhibitors, and that ABT-737 and bortezomib-induced cleavage of Bid into tBid was inhibited by a caspase-8 inhibitor, indicate the involvement of the extrinsic apoptotic pathway as well. Furthermore, apoptosis induced by the combination of ABT-737 and bortezomib occurred via caspase-dependent pathways as indicated by the fact that the pan-caspase inhibitor reduced the effect of ABT-737 and bortezomib on apoptosis. The mitochondrial apoptotic pathway is controlled by a balance between the proapoptotic protein members (i.e., the multidomain proapoptotic Bax, Bak, and BH3-only proapoptotic Bid, Bim, Bad, Bik, Noxa, Puma, Bmf, and Hrk) and antiapoptotic protein members (i.e., the multidomain antiapoptotic Bcl-2, Bcl-xL, Bcl-w, Mcl-1, and Bfl(A1) of the Bcl-2 family. Those multidomain Bcl-2 proteins are functionally regulated by the BH3-only proteins. Bid is localized in the cytosolic fraction of cells as an inactive precursor and tBid, the active form of Bid, is generated upon proteolytic cleavage by caspases (Gross et al., 1999; Wee et al., 2000). Experiments with caspase inhibitors indicated that in this system caspase-3 and caspase-8 mediates Bid cleavage.

Our studies clearly demonstrated that although PTEN-intact glioma cell lines were sensitive to the combination of ABT-737 and bortezomib, PTEN-deficient cell lines, such as U87 and LNZ308, were not. PTEN is a well studied tumor suppressor gene that is mutated or deleted in various cancers including glioma (Parsons et al., 2008). But not until more recently was PTEN, or the lack of it, implicated in the resistance of cancer cells to conventional radiation therapy and chemotherapy (Li et al., 1997; Hanahan and Weinberg, 2000; Knobbe et al., 2002; Omuro et al., 2007; Parsons et al., 2008; Hanahan and Weinberg, 2011). Akt is a potent antiapoptosis molecule common to both the PTEN and Bel-2 pathways (Pugazhenthi et al., 2000). In this study, we clearly demonstrate that Akt1 is a crucial mediator of bortezomib and ABT-737 resistance in PTEN-deficient glioma cells. Such a conclusion is based on several findings. The phosphorylation levels of Akt kinase were up-regulated in U87 and LNZ308 cell lines. Preincubation of U87 and LNZ308 cells with LY294002 or PI-103 (PI3K/Akt inhibitors) down-regulated Akt1 phosphorylation and restored sensitivity to bortezomib and ABT-737 by inducing Δψm and Bax activation. Similar results were observed when PTEN-deficient U87 and LNZ308 cells were infected with Ad-Akt 1 (DN) or Ad-PTEN and challenged with bortezomib + ABT-737.

The initiating stimulus leading to the change in Bax conformation caused by bortezomib and ABT-737 is as yet undetermined. The conformational change and translocation of Bax may also be regulated by the PI3K/Akt pathway, with active PI3K capable of maintaining a cytosolic Bax distribution (Yamaguchi and Wang, 2001). The activation of Bax, including Bax conformational changes and oligomerization, seems to play a crucial role in the initiation of bortezomib- and ABT-737-induced apoptosis. Our group has demonstrated that the activation of Bax, including Bax conformational changes and oligomerization, seems to play a crucial role in the initiation of apoptosis after other signaling-targeted therapies in gliomas. This effect could be counteracted by overexpression of constitutively active Akt, suggesting the critical involvement of Akt signaling pathways involved in Bax activation and apoptosis in glioma (Premkumar et al., 2010). A previous study proposed active Akt to affect the conformation of Bax and thus inhibit Bax oligomerization in the mitochondrial outer membrane (Yamaguchi and Wang, 2001). Another report presented evidence that Bax initially inserts into the mitochondrial outer membrane as a mono-
and Pollack. 

Annis MG, Soucie EL, Dlugosz PJ, Cruz-Aguado JA, Penn LZ, Leber B, and Andrews Aghajanian C, Soignet S, Dizon DS, Pien CS, Adams J, Elliott PJ, Sabbatini P, Miller demonstrate that down-regulation of Akt1 phosphorylation (by pharmacological or genetic manipulation) enhanced sensitivity to the inhibitors, strongly supporting the hypothesis that up-regulation of Akt1 is of primary importance for the bortezomib + ABT-737 resistance observed in PTEN-deficient glioma cells. Our data suggest that PI3K/Akt-dependent protection may occur upstream of mitochondria; thus, therapeutic strategies that target the PI3K/Akt pathway may be useful for cancers lacking PTEN function.
