Treatment with the 3-Ketoacyl-CoA Thiolase Inhibitor Trimetazidine Does Not Exacerbate Whole-Body Insulin Resistance in Obese Mice

Received February 23, 2014; accepted March 18, 2014

ABSTRACT

There is a growing need to understand the underlying mechanisms involved in the progression of cardiovascular disease during obesity and diabetes. Although inhibition of fatty acid oxidation has been proposed as a novel approach to treat ischemic heart disease and heart failure, reduced muscle fatty acid oxidation rates may contribute to the development of obesity-associated insulin resistance. Our aim was to determine whether treatment with the antianginal agent trimetazidine, which inhibits fatty acid oxidation in the heart secondary to inhibition of 3-ketoacyl-CoA thiolase (3-KAT), may have off-target effects on glycemic control in obesity. We fed C57BL/6NCrl mice a high-fat diet (HFD) for 10 weeks before a 22-day treatment with the 3-KAT inhibitor trimetazidine (15 mg/kg per day). Insulin resistance was assessed via glucose/insulin tolerance testing, and lipid metabolite content was assessed in gastrocnemius muscle. Trimetazidine-treatment led to a mild shift in substrate preference toward carbohydrates as an oxidative fuel source in obese mice, evidenced by an increase in the respiratory exchange ratio. This shift in metabolism was accompanied by an accumulation of long-chain acyl-CoA and a trend to an increase in triacylglycerol content in gastrocnemius muscle, but did not exacerbate HFD-induced insulin resistance compared with control-treated mice. It is noteworthy that trimetazidine treatment reduced palmitate oxidation rates in the isolated working mouse heart and neonatal cardiomyocytes but not C2C12 skeletal myotubes. Our findings demonstrate that trimetazidine therapy does not adversely affect HFD-induced insulin resistance, suggesting that treatment with trimetazidine would not worsen glycemic control in obese patients with angina.

Introduction

Ischemic heart disease is a major cause of death and disability in the world today. However, results from numerous epidemiologic studies and randomized, placebo-controlled trials have provided compelling evidence that ischemic heart disease is highly manageable. Current treatment regimens consist of either percutaneous or surgical techniques to restore myocardial blood and oxygen supply, or pharmacotherapy (i.e., β-adrenergic receptor blockers) to reduce myocardial oxygen demand, and have significantly improved the overall prognosis of patients with angina and/or ischemic heart disease (Anderson et al., 2013). Yet, there remains a significant number of patients who are refractory to conventional treatment, and thus, novel therapies to treat ischemic heart disease are necessary. One potential exciting new therapy involves the optimization of cardiac energy metabolism, which can be achieved via reducing myocardial fatty acid oxidation rates (Ussher and Lopaschuk, 2008; Jaswal et al., 2011; Ussher et al., 2012a).

Indeed, preclinical studies demonstrate that reducing fatty acid oxidation rates in the heart, either secondary to limiting the mitochondrial uptake of fatty acids, or directly inhibiting the mitochondrial β-oxidation enzymatic machinery, reduces infarct size and improves cardiac function in experimental models of ischemia/reperfusion injury (Kantor et al., 2000; Dyck et al., 2004; Ussher et al., 2012b). Similar findings have been recapitulated in humans, as treatment with either perhexiline, which restricts mitochondrial fatty acid uptake via inhibition of carnitine palmitoyl transferase–1, or trimetazidine, which directly inhibits fatty acid oxidation via inhibiting the mitochondrial β-oxidation enzyme long-chain 3-ketoacyl-CoA thiolase (3-KAT), improves left ventricular (LV) function in ischemic heart failure patients (Lee et al., 2005; Fragasso et al., 2006; Tuunanen et al., 2008).

This study was funded by a grant from the Heart and Stroke Foundation of Alberta (to D.M.M.); and the National Institutes of Health National Heart, Lung, and Blood Institute [Grant R01-HL101189] (to D.M.M.). J.R.U. is a trainee of the Alberta Heritage Foundation for Medical Research.

ABBREVIATIONS: ANOVA, analysis of variance; CPT-1, carnitine palmitoyl transferase 1; DAG, diacylglycerol; DMEM, Dulbecco’s modified Eagle’s medium; HFD, high-fat diet; 3-KAT, 3-ketoacyl-CoA thiolase; LV, left ventricular; RER, respiratory exchange ratio; T2D, type 2 diabetes; TAG, triacylglycerol.
The metabolic agents available that act via reducing fatty acid oxidation rates, trimetazidine is the best characterized (Kantor et al., 2000; Lopaschuk et al., 2003) and is used clinically in over 80 countries as a treatment for angina (Ciapponi et al., 2005; Ussher and Lopaschuk, 2006). Although reducing fatty acid oxidation rates in the heart may produce beneficial anti-ischemic effects, it has been demonstrated in muscle that decreased fatty acid oxidation rates may promote insulin resistance in the setting of obesity (Choi et al., 2007; Savage et al., 2007). During obesity, excessive fatty acid uptake outpaces mitochondrial oxidative capacity, and as esterified fatty acids are diverted away from carnitine palmitoyl transferase 1 (CPT-1), the rate-limiting enzyme in mitochondrial fatty acid uptake, triacylglycerol (TAG) and other lipid metabolites such as ceramide and diacylglycerol (DAG) accumulate, which may have direct negative effects on muscle insulin sensitivity (Shulman, 2000; Chavez and Summers, 2012; Muoio and Neuf, 2012).

Because of these contrasting views regarding fatty acid oxidation rates in heart and muscle, our objective was to determine whether treatment with trimetazidine would exacerbate insulin resistance induced by a high-fat diet (HFD). As patients with angina and ischemic heart disease are also often obese and at risk of type 2 diabetes (T2D), it is essential to determine whether trimetazidine may have off-target effects on insulin sensitivity that potentially limit its therapeutic utility.

Materials and Methods

Animal Studies. All animals received care according to the Canadian Council on Animal Care, and all animal procedures were approved by the University of Alberta Health Sciences Animal Welfare Committee. The 26-week-old C57BL/6NCrl mice (Charles River Laboratories, Hollister, CA) received a HFD (60% kcal from lard; Research Diets New Brunswick, NJ) for 10 weeks. At the end of week 10, animals were administered trimetazidine hydrochloride (15 mg/kg per day; Sigma-Aldrich, St. Louis, MO) or saline by intraperitoneal injection for 3 weeks (see Fig. 1 for the study protocol in obese mice). At study completion, ad libitum animals were killed for tissue extraction via intraperitoneal injection of sodium pentobarbital (12 mg) 2 hours into their dark cycle.

Glucose and Insulin Tolerance. Intraperitoneal glucose and insulin tolerance tests were performed 6 hours after food withdrawal using glucose and insulin doses of 2 g/kg and 0.7 U/kg, respectively. Blood glucose levels were determined at 0, 20, 30, 60, and 90 minutes after glucose/insulin administration via tail bleed with the Accu Check Advantage system (Roche Applied Science, Indianapolis, IN).

Plasma Insulin Levels. Plasma insulin concentrations were determined via use of a commercially available enzymatic assay kit (Alpco Diagnostics, Salem, NH) as previously described elsewhere (Bates et al., 2012). In brief, 5 μl of sample was added per well with 75 μl of a provided enzyme conjugate, and the 96-well plate was then incubated for 2 hours at room temperature on an orbital microplate shaker. After incubation, the plate was washed six times with wash buffer, and then 100 μl of a provided substrate was added to each well to start the reaction, which was terminated after 30 minutes via addition of 100 μl of stop solution. Air bubbles were removed, and the plasma insulin levels (ng/ml) were determined via reading the absorbance of the plate at a 450 nm wavelength.

Isolated Working Heart Perfusions. Mice were anesthetized with sodium pentobarbital (60 mg/kg i.p.), and the hearts were subsequently excised for perfusion in the isolated working heart mode, as previously described elsewhere (Ussher et al., 2012b). In brief, hearts were perfused with oxygenated Krebs-Henseleit solution consisting of 5.0 mM glucose, 0.4 mM palmitate bound to 3% fatty acid-free bovine serum albumin, and 100 μU/ml insulin. The perfusate was labeled with [U-14C]glucose and [9,10-3H]palmitate, and 14CO2 production was assessed for the measurement of glucose and palmitate oxidation as previously described elsewhere (Ussher et al., 2012b).

Muscle Metabolic Profiling. Gastrocnemius muscle and liver extracts for quantification of acylcarnitine (mass spectrometry/gas chromatography), long-chain acyl-CoA (high-performance liquid chromatography), TAG (chloroform/methanol extraction), DAG (DAG kinase thin-layer chromatography assay), and ceramide (DAG kinase thin-layer chromatography assay) content were determined as previously described elsewhere (Ussher et al., 2010).

Indirect Calorimetry. In vivo whole-body metabolic assessment was performed using an Oxymax Comprehensive Laboratory Animal Monitoring System (Columbus Instruments, Columbus, OH) to determine the respiratory exchange ratio, oxygen consumption rates, heat production, locomotor activity, and 24-hour food intake, as previously described elsewhere (Ussher et al., 2010). Animals were initially acclimatized in the system for a 24-hour period; the subsequent 24-hour period was used for data collection.

Exercise Capacity. Exercise capacity was performed by running mice on a calibrated, motor-driven treadmill (Columbus Instruments) at a speed of 3 m/min for 1 minute, followed by increasing speeds of 4 m/min for 1 minute, 5 m/min for 1 minute, 6 m/min for 3 minutes, 8 m/min for 14 minutes, 9 m/min for 10 minutes, 10 m/min for 7 minutes, 12 m/min for 7 minutes, and 14 m/min until exhaustion. The first 6 minutes were used as an acclimatization period for the animals to become familiar with the treadmill and were not used for data collection. Exhaustion was determined as the animal spending >5 consecutive seconds on the shock grid, or the animal running off the shock grid and immediately falling back onto the shock grid three consecutive times.

Cell Culture. Primary rat cardiomyocytes were isolated from the hearts of 1- to 3-day-old neonatal rat pups (Biosciences) and cultured in Dulbecco’s modified Eagle’s medium (DMEM)/Ham’s Nutrient Mixture F-12 containing 5% fetal bovine serum, 10% horse serum, and 1% penicillin-streptomycin, as previously described elsewhere (Samokhvalov et al., 2012). The C2C12 myotubes [CRL-1772; American Type Culture Collection (ATCC), Manassas, VA] were cultured as myoblasts on Primeria six-well plates (Falcon, Corning Life Sciences, Tewksbury, MA) with DMEM containing 10% fetal bovine serum and 1% penicillin-streptomycin, whereas myotube differentiation was induced using DMEM containing 2% horse serum and 1% penicillin-streptomycin, as previously described (Ussher et al., 2009). Muscle biopsies from vastus lateralis of lean women were extracted via the percutaneous needle biopsy technique, and cultured myoblasts from the biopsy samples were subsequently differentiated into skeletal myocytes, as previously described elsewhere (Kovalik et al., 2011). For the glucose and palmitate oxidation experiments, the medium was switched to Krebs-Henseleit solution consisting of 11.0 mM glucose and 0.8 mM palmitate bound to 4% fatty acid-free bovine serum albumin. The Krebs-Henseleit solution was labeled with either [U-14C]glucose or [1-14C]palmitate, and 14CO2 was captured in hyamine hydroxide-soaked filter paper for the measurement of glucose and palmitate oxidation in separate experiments, as previously described elsewhere (Samokhvalov et al., 2012). Oleate oxidation in human skeletal myocytes was also measured, as previously described elsewhere (Kovalik et al., 2011).

Statistical Analysis. The significance of differences between two groups was determined by the use of an unpaired, two-tailed Student’s t test. The significance of differences for multiple comparisons was estimated by two-way analysis of variance (ANOVA). When ANOVA revealed differences, multiple t tests with a Bonferroni correction were performed on the data sets. P < 0.05 was considered statistically significant.
Results

Trimetazidine Treatment Mildly Affects Substrate Preference In Vivo without Affecting Body Weight, Adiposity, or Glycemia in HFD-Induced Obese Mice. As expected, mice fed a HFD for 10 weeks experienced a significant increase in weight gain (Fig. 2A) and became glucose intolerant (Fig. 2B). Starting at week 11, animals received daily injections of either trimetazidine (15 mg/kg) or saline for 22 days. Body weight was not altered in trimetazidine-treated HFD-induced obese mice after 1 week (Fig. 2C) or after study completion in either obese (44.85 ± 1.31 g versus 43.77 ± 1.16 g) or lean mice (28.68 ± 0.99 g versus 27.64 ± 0.35 g). Likewise, overall adiposity as determined by measurement of epididymal and perirenal adipose depot weights was unaffected in trimetazidine-treated HFD-induced obese mice after animal sacrifice at 22 days after treatment (Fig. 2, D and E). Furthermore, plasma TAG and free fatty acid levels were similar in trimetazidine-treated HFD-induced obese mice after a 6-hour fast at day 21 after treatment, whereas plasma TAG levels were elevated with no change in free fatty acid levels ad libitum at day 22 after treatment (Fig. 2, F and G; Table 1).

At days 16 and 17 after treatment, indirect calorimetry was assessed through use of metabolic cages, whereby saline-treated HFD-induced obese mice exhibited a respiratory exchange ratio (RER) approaching 0.7, indicative of fatty acid oxidation as their primary metabolic substrate. Interestingly, treatment of HFD-induced obese mice with trimetazidine induced a mild shift in metabolic substrate preference, as seen by an increase in RER during the light cycle (Fig. 2, H and I), illustrating a greater reliance on carbohydrates for oxidative energy metabolism. This shift in metabolism in trimetazidine-treated HFD-induced obese mice was not associated with alterations in whole-body oxygen consumption rates, heat production, locomotor activity (Fig. 2, J–L), or exercise capacity (14.09 ± 2.86 minutes versus 14.70 ± 3.11 minutes during treadmill running) and food intake (2.42 ± 0.17 g versus 2.35 ± 0.19 g over 24 hours). Moreover, this mild effect on substrate preference after trimetazidine treatment did not worsen insulin resistance, as glucose tolerance at both 7 and 21 days after treatment was similar between saline- and trimetazidine-treated HFD-induced obese mice (Fig. 3, A and B), as were plasma insulin levels during the glucose tolerance test (data not shown). Likewise, insulin tolerance at 14-days after treatment was also comparable between saline and trimetazidine-treated HFD-induced obese mice (Fig. 3, C and D).

Trimetazidine Inhibits Fatty Acid Oxidation in Cardiac but Not Skeletal Muscle. Palmitate oxidation was significantly inhibited in trimetazidine-treated (100 μM) isolated working mouse hearts, which was associated with a corresponding increase in glucose oxidation (Fig. 4A). Similar findings were observed in cultured neonatal rat cardiomyocytes (10 μM trimetazidine, Fig. 4B). In contrast, trimetazidine (10 μM) did not inhibit palmitate oxidation in C2C12 skeletal muscle myotubes (Fig. 4C). It is noteworthy, however, that trimetazidine did stimulate glucose oxidation in C2C12 myotubes (Fig. 4C), similar to its effect in the heart (Fig. 4A). In addition, we observed a significant decrease in oleate oxidation in primary cultured human myocytes treated with the CPT-1 inhibitor oxefunicie, but not in response to treatment with trimetazidine (Fig. 4, D and E).

Muscle and Hepatic Lipid Metabolite Content in HFD-Induced Obese Mice after 22 Days of Treatment with Trimetazidine. Treatment with trimetazidine for 22 days resulted in a trend to an increase in gastrocnemius TAG content, which was accompanied by a significant increase in gastrocnemius long-chain acyl-CoA content (Fig. 5, A and B). In contrast, trimetazidine treatment had no effect on gastrocnemius DAG or ceramide content (Fig. 5, C and D). Gas chromatography/mass spectrometry metabolic profiling of gastrocnemius muscle from control and trimetazidine-treated HFD-induced obese mice demonstrated no change in any of the intermediates of the tricarboxylic acid cycle (Fig. 5E). Although the majority of long-chain acylcarnitine species such as palmitoyl- and stearoylcarnitine did not accumulate further in gastrocnemius muscle of HFD-induced obese mice treated with trimetazidine (data not shown), there was a trend to a further increase in other long-chain acylcarnitine species such as palmitoleoylcarnitine (Fig. 5, F and G). Furthermore, a number of plasma long-chain acylcarnitine species were increased in trimetazidine-treated HFD-induced obese mice, consistent with trimetazidine inhibiting muscle fatty acid oxidation in vivo (Fig. 5, H and I). On the contrary, we observed no differences in hepatic TAG, long-chain acyl-CoA, or ceramide content in HFD-induced obese mice treated with trimetazidine for 22 days (Fig. 6).

Discussion

This study demonstrates that treatment with the 3-KAT inhibitor trimetazidine does not exacerbate HFD-induced...
Fig. 2. Treatment with trimetazidine has no effect on body weight in HFD-induced obese mice but induces a shift in energy substrate metabolism away from fatty acids and toward carbohydrates as an oxidative energy source in vivo. Body weight (A) and glucose intolerance (B) in mice after 10 weeks of high-fat feeding. (C) Body weight of HFD-induced obese mice at 7 days after treatment. Epididymal (D) and perirenal (E) fat pad weight (normalized to body weight) at the time the animals were killed in saline- and trimetazidine-treated HFD-induced obese mice. Plasma TAGs (F) and free fatty acids (FFAs) (G) in the ad libitum state (day 22 after treatment) and fasted state (day 21 after treatment) from HFD-induced obese mice treated with saline or trimetazidine. Respiratory exchange ratio (H—I), whole-body oxygen consumption rates (J), whole-body heat production (K), and locomotor activity (L) in HFD-induced obese mice at days 16–17 after treatment. Values represent mean ± S.E. (n = 5–6). The statistical significance of differences between the two groups was determined by the use of an unpaired, two-tailed Student’s t test. The significance of differences for multiple comparisons was estimated by two-way analysis of variance (ANOVA). When ANOVA revealed differences, multiple t tests with a Bonferroni correction were performed on the data sets. *P < 0.05, statistically significantly different from lean/pre–HFD mice. †P < 0.05, statistically significantly different from saline-treated HFD-induced obese mice.
advantage of mitochondrial oxidative rates (Neely et al., 1967). Indeed, our palmitate oxidation rates measured in both neonatal rat cardiomyocytes and C2C12 myotubes are substantially lower than the rates obtained in our isolated working mouse hearts, which may increase the difficulty of capturing an actual inhibition of fatty acid oxidation. Furthermore, we have previously shown that the ability to measure inhibition of fatty acid oxidation via trimetazidine in vitro is complicated by the accumulation of substrate for 3-KAT over time, which overcomes trimetazidine-mediated inhibition of 3-KAT (Lopaschuk et al., 2003). Whether the kinetics for trimetazidine-mediated inhibition of 3-KAT are different in neonatal cardiomyocytes and C2C12 myotubes is of interest but is beyond the scope of this study’s objectives.

To support our indirect calorimetry observations, we used targeted metabolomics to quantify gastrocnemius and plasma acylcarnitines as an index of potential alterations in fatty acid oxidation. With trimetazidine-mediated inhibition of 3-KAT, the last enzyme involved in mitochondrial fatty acid oxidation, fatty acids would still have free access into the mitochondria through CPT-1, thereby allowing partial oxidation. This is evidenced by similar levels of long-chain acylcarnitines in gastrocnemius muscle from both vehicle control and trimetazidine-treated animals. As skeletal muscle has been demonstrated to be a major source of circulating acylcarnitines (Noland et al., 2009), measurement of plasma acylcarnitines should also provide an index of intramuscular acylcarnitine accumulation and perturbations in fatty acid flux. Indeed, plasma long-chain

insulin resistance, even though trimetazidine treatment resulted in a greater accumulation of intramuscular TAG and long-chain acyl-CoA. As previous findings have suggested that a reduction in skeletal muscle fatty acid oxidation can cause insulin resistance and T2D (Choi et al., 2007; Savage et al., 2007), our goal was to determine whether treatment with trimetazidine might have off-target adverse effects on muscle insulin resistance and glycemic control. Surprisingly, although trimetazidine inhibited fatty acid oxidation rates in the isolated working mouse heart and cultured neonatal cardiomyocytes, trimetazidine did not inhibit fatty acid oxidation rates in cultured muscle myotubes, which may explain why trimetazidine did not worsen HFD-induced insulin resistance. However, our in vivo indirect calorimetry findings suggest a mild inhibition of whole-body fatty acid oxidation rates, evidenced by the small increase in RER after treatment with trimetazidine, consistent with the increase in intramuscular lipid accumulation. Although indirect calorimetry reflects whole-body metabolism, a significant fraction of the RER is accounted for by skeletal muscle oxidative metabolism (Zurlo et al., 1990; Sleigh et al., 2011).

A potential limitation that may account for the discrepancy between our in vivo and in vitro findings involves the inherent low oxidative rates measured in the in vitro cell culture systems. Indeed, nanomoles per minute rates in vitro (An et al., 2006; Watt et al., 2009), measurement of plasma acylcarnitines should also provide an index of intramuscular acylcarnitine accumulation and perturbations in fatty acid flux. Indeed, plasma long-chain

Acylcarnitines were elevated in mice after treatment with trimetazidine, consistent with 3-KAT inhibition not impeding CPT-1-mediated mitochondrial fatty acid uptake, enhancing the accumulation of intramuscular long-chain acylcarnitines and their subsequent export into the circulation.

Therefore, on the basis of our in vivo observations, we do believe that treatment with trimetazidine results in a very mild inhibition of muscle fatty acid oxidation, which is not captured in our in vitro studies likely due to lack of sensitivity. To our surprise, however, this does not result in a worsening of HFD-induced insulin resistance. Although current dogma demonstrates that an increase in fatty acid oxidation reduces glucose oxidation and subsequent glucose uptake in the isolated perfused heart and diaphragm, although these conclusions were simply extrapolated to skeletal muscle. In contrast, meticulous work from the Shulman laboratory suggests that fatty acid oxidation rates are impaired in muscle in the setting of obesity, and that accelerating fatty acid oxidation may improve glucose homeostasis in obesity via reducing the accumulation of lipid metabolites and subsequent inhibition of insulin signaling (Choi et al., 2007; Savage et al., 2007; Zhang et al., 2007).

Likewise, muscle overexpression of CPT-1 via electroporation of an adenovirus increases fatty acid oxidation rates and reduces membrane accumulation of DAG/ceramide, which...

results in a significant improvement in insulin signaling and glucose uptake in rats fed a HFD (Bruce et al., 2009). Indeed, long-term inhibition of CPT-1 in rats with etomoxir increases muscle lipid accumulation, which is associated with a worsening of obesity-induced insulin resistance (Dobbins et al., 2001). On the other hand, we have shown in a mouse model of diet-induced obesity that a 4-week treatment with the CPT-1 inhibitor oxfenicine reverses insulin resistance and glucose intolerance (Keung et al., 2013). Reasons for this discrepancy are not clear but may be attributed to species-related differences or CPT-1 inhibition being provided at the onset of high-fat feeding in the etomoxir study (Dobbins et al., 2001), whereas we allowed mice to become obese and insulin resistant before treating with oxfenicine (Keung et al., 2013).

In support of our studies, Finck et al. (2005) have shown that elevated fatty acid oxidation rates in mice overexpressing muscle-specific peroxisome proliferator–activated receptor α induce insulin resistance, and that this can also be improved via treatment with the CPT-1 inhibitor oxfenicine. Studies in humans consuming a HFD for 3 days have recapitulated these effects, as treatment with etomoxir (five doses totaling 600 mg spread over 36 hours) inhibited fatty acid oxidation, which was associated with a corresponding increase in glucose oxidation, sarcolemmal glucose transporter type 4 (GLUT4) content in muscle fibers, and a lowering in the homeostatic model assessment (HOMA) index scores (Timmers et al., 2012).

A key difference between our observations and the aforementioned studies where inhibiting fatty acid oxidation has beneficial effects on muscle insulin sensitivity involves the method of inhibition. Indeed, we used a 3-KAT inhibitor (trimetazidine) in this particular study, whereas the other studies inhibited fatty acid oxidation secondary to an inhibition of CPT-1 and subsequent mitochondrial fatty acid uptake (Finck et al., 2005; Timmers et al., 2012; Keung et al., 2013). It has been suggested that lipid overload specifically in the mitochondria elicits mitochondrial dysfunction, increases oxidative stress, and impairs insulin sensitivity in muscle (Koves et al., 2008; Anderson et al., 2009). Thus, restricting mitochondrial fatty acid uptake versus directly inhibiting mitochondrial β-oxidation should not yield equivalent biologic outcomes, as lipids may still enter the mitochondria if the inhibition takes place at the level of β-oxidation. Nevertheless, the discordant results of these multiple studies collectively illustrates the need for further work to elucidate exactly how alterations in fatty acid oxidation affect the development and progression of muscle insulin resistance.

The fact that intramuscular ceramide and DAG content did not increase further after 3-KAT inhibition may also explain why insulin resistance was not exacerbated in our model. At the same time, it may also be possible that an additional accumulation of muscle lipid metabolites (i.e., 10–20% further increase) would not impart any further damage on glucose/insulin tolerance beyond that already attributed to the muscle lipid metabolites accumulated after HFD-induced obesity. Indeed, our model of HFD-induced obesity causes a doubling in the levels of muscle long-chain acyl-CoA compared with standard chow-fed mice (Ussher et al., 2010), and hence the additional increase after trimetazidine treatment may not yield any further consequences on glucose tolerance and insulin sensitivity.

Although inhibition of 3-KAT-regulated fatty acid oxidation may not be harmful in our study, it is important to note that the inhibition of fatty acid oxidation in liver may have detrimental effects, potentially accelerating steatosis development (Savage et al., 2007). Nonetheless, we did not observe any further increase in hepatic TAG, long-chain acyl-CoA, or ceramide content in trimetazidine-treated HFD-induced obese mice. Adiposity was also similar in our study, as treatment of obese mice with trimetazidine did not increase epididymal or perirenal fat pad weight.

Conversely, it is also possible that life-long modest reductions in fatty acid oxidation, such as which may occur in obese patients with ischemic heart disease who may be treated with trimetazidine over years or decades, may ultimately result in impaired insulin sensitivity. However, the answer to that question cannot be determined from this study, which only investigated the effects of a 3-week treatment regimen with trimetazidine on HFD-induced metabolic dysfunction. This treatment duration was chosen as we were concurrently investigating a separate cardiovascular study, determining whether trimetazidine therapy could alleviate obesity-induced cardiac dysfunction.

Ultrasound echocardiography analyses at day 20 after treatment revealed a significant amelioration of diet-induced cardiac hypertrophy (6.43 ± 0.50 g/mm versus 4.98 ± 0.46 g/mm

LV mass/tibia length) and contractile dysfunction in HFD-induced obese mice receiving trimetazidine (data not shown). These results are consistent with findings from Tuunanen et al. (2008), whereby treatment of idiopathic dilated cardiomyopathy patients with trimetazidine caused a modest 10% decrease in myocardial fatty acid oxidation rates but a significant improvement in LV function. These authors also showed that trimetazidine inhibits endogenous TAG-derived fatty acid oxidation, consistent with the trend to increased gastrocnemius TAG content that we observed in HFD-induced obese mice treated with trimetazidine (Bucci et al., 2011). Therefore, it appears that the antiangiogenic agent trimetazidine elicits cardioprotection in the setting of obesity without adversely affecting muscle insulin sensitivity, though a more prolonged treatment may yield different results.

Overall, our results reveal important insights regarding the contribution of fatty acid oxidation to insulin resistance. It has been postulated that impaired skeletal muscle fatty acid oxidation can cause insulin resistance (Savage et al., 2007). Thus, treatment with trimetazidine in obese mice would be anticipated to exacerbate skeletal muscle insulin resistance, which we did not observe, suggesting that trimetazidine would not impair insulin sensitivity in obese patients with angina. Furthermore, our observations in vitro demonstrate that, unlike in the heart, trimetazidine’s effect on muscle fatty acid oxidation is extremely mild. In spite of the ongoing debate concerning reduced fatty acid oxidation rates and insulin resistance, our findings do not raise caution regarding the use of trimetazidine to treat obese patients with angina.

Acknowledgments
The authors thank the dedicated staff of the Metabolomics and Biomarker Core of the Sarah W. Stedman Nutrition and Metabolism Center for measurement of acylcarnitines and tricarboxylic acid cycle intermediates, and the Cardiovascular Translational Research Centre HPLC Core Facility for the measurement of long-chain acyl-CoAs and ceramides.

Authorship Contributions
Participated in research design: Ussher, G.D. Lopaschuk.
Performed data analysis: Ussher, Jaswal, Muoio, G.D. Lopaschuk.
Wrote or contributed to the writing of the manuscript: Ussher, Keung, Jaswal, Muoio, G.D. Lopaschuk.
