ABSTRACT

Gestational diabetes mellitus is a major complication of human pregnancy. The oral clearance (CL) of glyburide, an oral antidiabetic drug, increases 2-fold in pregnant women during late gestation versus nonpregnant controls. In this study, we examined gestational age–dependent changes in maternal-fetal pharmacokinetics (PK) of glyburide and metabolites in a pregnant mouse model. Nonpregnant and pregnant FVB mice were given glyburide by retro-orbital injection. Maternal plasma was collected over 240 minutes on gestation days (gd) 0, 7.5, 10, 15, and 19; fetuses were collected on gd 15 and 19. Glyburide and metabolites were quantified using high-performance liquid chromatography–mass spectrometry, and PK analyses were performed using a pooled data bootstrap approach. Maternal CL of glyburide increased approximately 2-fold on gd 10, 15, and 19 compared with nonpregnant controls. Intrinsic CL of glyburide in maternal liver microsomes also increased as gestation progressed. Maternal metabolite/glyburide area under the curve ratios were generally unchanged or slightly decreased throughout gestation. Total fetal exposure to glyburide was <5% of maternal plasma exposure, and was doubled on gd 19 versus gd 15. Fetal metabolite concentrations were below the limit of assay detection. This is the first evidence of gestational age–dependent changes in glyburide PK. Increased maternal glyburide clearance during gestation is attributable to increased hepatic metabolism. Metabolite elimination may also increase during pregnancy. In the mouse model, fetal exposure to glyburide is gestational age–dependent and low compared with maternal plasma exposure. These results indicate that maternal-glyburide therapeutic strategies may require adjustments in a gestational age–dependent manner if these same changes occur in humans.

Introduction

Gestational diabetes mellitus (GDM) complicates 5–14% of human pregnancies (Jovanovic and Pettitt, 2001; Paglia and Coustan, 2011). Like type 2 diabetes, the pathology of GDM is a combination of increased insulin resistance and decreased insulin sensitivity. If left untreated, GDM poses significant risks to the mother, fetus, and neonate. Such risks include maternal hypertension, preeclampsia, and cesarean delivery, as well as fetal/neonatal morbidities including macrosomia, hypoglycemia, and increased risk of metabolic syndrome, type 2 diabetes, and obesity for the offspring later in life (American College of Obstetricians and Gynecologists Committee on Practice Bulletins—Obstetrics, 2001; HAPO Study Cooperative Research Group, 2002). While insulin resistance occurs in normal pregnancy, women with GDM experience insulin resistance beyond their ability to compensate with increased insulin production, leading to hyperglycemia. Although insulin has been the standard of care for pharmacotherapeutic treatment of GDM, oral antidiabetic agents, such as glyburide, have gained increasing popularity because of their ease of
Diagnosis of GDM generally takes place during the second trimester of pregnancy. It is well established that physiologic, biochemical, and hormonal changes during pregnancy can alter the pharmacokinetics (PK) of drugs throughout gestation (e.g., increased hepatic blood flow and glomerular filtration, and/or changes in the expression of drug-metabolizing enzymes and transporters) (Klieger et al., 2009). However, data are quite limited regarding the PK of glyburide during pregnancy, particularly in relation to gestational age. One study estimated a 2-fold increase in the oral clearance of glyburide in women with GDM in the third trimester of pregnancy compared with nonpregnant women with type 2 diabetes mellitus (Hebert et al., 2009). Formation clearance of 4-trans-hydroxy-cyclohexyl glyburide (M1), a pharmacologically active metabolite, was also increased more than 2-fold in the GDM group. Glyburide crosses the human placenta, but at a much slower rate compared with the placental transfer marker antipyrine (Nanovskaya et al., 2006), which was not expected given the low molecular weight and high lipophility of glyburide. This low rate of placental transfer could be explained by extremely high plasma protein binding of glyburide (Nanovskaya et al., 2006) and efflux transport at the apical membrane of the syncytiotrophoblasts in humans and mice. The ATP-binding cassette transporters breast cancer resistance protein (BCRP) and P-glycoprotein (P-gp) have been implicated as placental barriers to glyburide (Gedeon et al., 2006, 2008b; Zhou et al., 2008; Hemauer et al., 2010). Although multidrug resistance proteins (MRP1 and MRP3) also transport glyburide (Gedeon et al., 2006; Hemauer et al., 2010), human placenta perfusion studies suggest that MRPs may only play a minor role in the transport of glyburide across human placenta (Gedeon et al., 2008a). The time course and mechanism by which pregnancy changes glyburide PK throughout gestation remain largely unexplained. Therefore, the main objective of this study was to investigate gestational age–dependent changes in maternal-fetal disposition of glyburide and the mechanisms behind these changes.

Since hepatic CYP3A and CYP2C9 activities are significantly induced during human pregnancy (Hebert et al., 2008; Feghali and Mattison, 2011), cytochrome P450 induction could be one possible mechanism for the increased maternal glyburide clearance during pregnancy. Like in humans, glyburide clearance in pregnant mice was similarly doubled on gestation day (gd) 15 compared with nonpregnant controls (Zhou et al., 2010b), suggesting that the pregnant mouse may be an appropriate animal model to study glyburide PK during pregnancy. The mRNA levels of several hepatic Cyp3a isoforms and CYP3A activity in pregnant mice are significantly increased in a gestational age–dependent manner compared with nonpregnant controls (Zhang et al., 2008; Shuster et al., 2013). Therefore, we used pregnant mice to study gestational age–dependent effects on maternal-fetal disposition of glyburide.

In vitro microsomal incubation studies suggest that glyburide is extensively metabolized in the human liver by CYP3A4, CYP2C9, and CYP2C19 to six major metabolites: M1, 4-cis-hydroxycyclohexyl glyburide (M2a), 3-cis-hydroxy-cyclohexyl glyburide (M2b), 3-trans-hydroxycyclohexyl glyburide (M3), 2-trans-hydroxy-cyclohexyl glyburide (M4), and ethylene-hydroxylated glyburide (M5) (Ravindran et al., 2006; Zharikova et al., 2009). Because M1 and M2b are potentially pharmacologically active (Rydberg et al., 1994) and limited data exist regarding metabolite PK in pregnant and nonpregnant individuals, we also examined maternal-fetal disposition of metabolites.

In this study, we first determined the maternal-fetal PK of glyburide and its metabolites throughout gestation in pregnant mice. We then investigated whether the intrinsic clearance of glyburide in microsomes isolated from the livers of pregnant mice was increased in a gestational age–dependent manner. The data obtained in this study will facilitate mechanistic understanding of changes in maternal-fetal PK of glyburide and its metabolites throughout gestation, which is imperative for gestational age–dependent therapeutic strategies.
(n = 3–5 per time point) were euthanized under anesthesia by cardiac puncture (i.e., a total of approximately 30 samples for each gestation day). Maternal blood was collected in heparinized microcentrifuge tubes (BD Biosciences, San Jose, CA) and centrifuged at 1000g for 10 minutes at 4°C. Plasma was collected and stored at −80°C until further analysis. Individual whole fetuses were collected from mice dosed on gd 15 and 19. Maternal mouse livers were also collected (n = 5 to 6 per gestation day) for microsomal preparation from mice that had been dosed with glyburide. Tissues were immediately rinsed with PBS, snap-frozen in liquid nitrogen, and stored at −80°C until use.

**Quantification of Glyburide and Metabolites in Maternal Plasma and Fetal Homogenates.** Glyburide and metabolite quantification in maternal plasma and fetal homogenates was performed using a previously validated high-performance liquid chromatography–mass spectrometry (HPLC-MS) method with some modifications (Narahrasetti et al., 2007). Most notable was the use of protein precipitation for the isolation of glyburide and metabolites from maternal plasma and fetal homogenates in place of liquid–liquid extraction. In brief, for every 100 µl maternal plasma, 450 µl methanol and 20 µl working internal standards (0.5 ng/µl glyburide-d11 and 0.15 ng/µl 4-trans-hydroxycyclohexyl glyburide-d3,13C) were added into a 1.5-ml microcentrifuge tube. Plasm samples were briefly vortexed and centrifuged at 20,800g for 10 minutes at 4°C. Supernatants were transferred to disposable clean glass tubes and evaporated using nitrogen gas. Samples were reconstituted in 75 µl initial mobile phase and 2 µl was injected per sample for HPLC-MS analysis. A calibration curve was prepared identically using human plasma as a matrix with a dynamic range of 10–4000 ng/ml for glyburide and 1.2–120 ng/ml for M1–M3.

Individual whole fetuses were homogenized in 1.5–2.5 ml PBS using an Omni Bead Ruptor Homogenizer (Omni International, Kennesaw, GA). For every 500 µl fetal homogenates, 50 µl 2 M HCl, 4 ml 60/40 (v/v) n-hexane/methylene chloride, and 20 µl working internal standard (0.5 ng/µl glyburide-d11) were added in a 13 × 100-mm borosilicate glass culture tube. Fetal samples were vortexed 30 seconds and centrifuged at 1970g for 10 minutes at 4°C. Supernatants were transferred to disposable clean glass tubes and evaporated using nitrogen gas. Each sample was reconstituted in 75 µl 1% formic acid in methanol and 2 µl was injected per sample for HPLC-MS analysis. A calibration curve for glyburide was prepared using 500 µl blank fetal homogenate (matched by gestational age) as the matrix, over a dynamic range of 0.05–2 ng glyburide. Calibration according to the analyte amount was chosen for fetall tissue analysis to accommodate the variations in fetall tissue specimen size and homogenate dilutions. No matrix effect was observed; that is, glyburide extraction recovery and instrument response did not vary over the range of fetal homogenate concentrations prepared on samples taken from gd 15 and 19 (0.06–0.6 g fetus/ml PBS).

The previously validated HPLC-MS method did not include M2a and M3 for lack of commercially available standards at the time (Narahrasetti et al., 2007). Those standards are now available; therefore, we modified the above method slightly to incorporate the separation and quantification of M1–M3 in maternal plasma. These metabolites were quantifiable in maternal plasma, but were not detectable in fetal tissue samples.

In brief, HPLC-MS was performed using an Agilent series 1100 high-performance liquid chromatographer interfaced with an Agilent G1956B single quadrupole mass spectrometer (Agilent Technologies, Palo Alto, CA). Separation of glyburide and all metabolites in maternal plasma, but were not detectable in fetal tissue samples.

volume in milliliters and the amount of microsomal protein in milligrams): 

$$CL_{\text{int}} = \frac{[d_{\text{dep}} \times \text{incubation volume}]}{\text{amount of microsomal protein}}$$

Statistically significant differences of $CL_{\text{int}}$ between gd 0 and other gestation days were determined using the Kruskal–Wallis test followed by the Dunn’s multiple comparison test assuming a significance level of 0.05.

**Quantification of Glyburide in Mouse Liver Microsomes.** Chromatographic separation of glyburide in extracts of mouse liver microsomal incubates was achieved using an Agilent Extend C18 column (50 mm × 2.1 mm, 5 μm) with gradient elution. The mobile phases consisted of methanol (B) and water containing 0.1% formic acid (A). The flow rate was set to 0.4 mL/min. The gradient was 30% methanol for the first 2 minutes, increased linearly to 75% for 3 minutes, held for 1 minute at 75% methanol, and finally decreased back to 30% for the remainder of the 9-minute run time. The mass spectrometer was run in atmospheric pressure ionization-electrospray positive ionization mode with a capillary voltage of 3500 V and a fragmentation voltage of 90 V for glyburide and glipizide. The drying gas temperature was 350°C, the nitrogen drying gas flow rate was 10 L/min, and the nebulizer pressure was 35 psi. Ions monitored were 498 m/z for glyburide and 446 m/z for glipizide.

**Pharmacokinetic and Statistical Analysis of Glyburide and Metabolites in Pregnant Mice.** Maternal PK parameters were estimated for each gestation day using a pooled data bootstrap method as previously described (Mager and Göller, 1998) with some modifications. Briefly, the following steps were used to obtain PK parameter estimates. First, concentration time points from one gd group were sampled randomly with replacement 30 times using R programming software (R Statistical Computing, Vienna, Austria; R Core Team, 2014). Second, a two-compartment model was fit to the bootstrapped pseudo-concentration time profiles using the following equation and the following upper constraint: $C_t = Ae^{-\alpha t} + Be^{-\beta t} (A + B ≤ 12,500 \text{ng mL}^{-1})$, where $C_t$ is the plasma concentration at time $t$ after dosing. The upper constraint for the sum of $A$ and $B$ was set to the highest possible blood concentration of glyburide in a 20-g female mouse given a 20 mg/ kg intraperitoneal dose (i.e., 20 μg distributed in a blood volume of 1.6 mL or 8% of mouse total body weight). Third, $A$, $B$, $\alpha$, and $\beta$ and average body weight of the mice in the given pseudo-profile were used to calculate area under concentration time curves from 0 to 240 minutes ($\text{AUC}_{0-240}$ min), $CL_{\text{int}}$ and $\text{Vss}$, central volume of distribution with and without body weight normalization ($\text{CL}_{\text{int}}$) and $\text{Vss}$, central volume of distribution at steady state or $\beta$ phase with and without body weight normalization ($\text{Vss}_{\beta}$), and body residence time. The average body weight of the mice used to generate the pseudo-profile was used to calculate body weight normalized estimates of clearance and volume of distribution. Fourth, steps 1–3 were repeated 10,000 times to create a distribution of PK parameter estimates. Fifth, based on the distribution of PK parameter estimates, 95% confidence intervals were obtained for all PK parameters. The above five steps were repeated for all gd groups. To determine whether PK parameters for pregnant mice (gd 7.5, 10, 15, and 19) were significantly different from those of nonpregnant mice (gd 0), we calculated two-sided $t$-tests with $P$ values using permutation tests with 10,000 replications (Westfall and Young, 1993). If the $P$ value was less than 0.05, the difference was considered statistically significant.

The maternal metabolite area under the curve (AUC) for each gd group and fetal glyburide AUC for gd 15 and 19 were estimated using the same above-described bootstrapping method. Fetal glyburide concentrations were determined in individual fetuses and averaged by litter prior to bootstrap analysis. Due to the complexity of maternal metabolite kinetics and fetal glyburide kinetics, only noncompartmental analyses were feasible. We chose to estimate AUCs using the linear trapezoidal rule. To evaluate whether compartmental and noncompartmental approaches produce comparable results, the AUCs of glyburide in maternal plasma were estimated using noncompartmental analysis as well. This allowed calculations of the maternal metabolite to glyburide AUC ratios as well as the fetal/maternal glyburide AUC ratios. Statistical significance between maternal metabolite AUCs and metabolite to glyburide AUC ratios estimated on gd 7.5, 10, 15, or 19 versus gd 0 were determined as described in the above paragraph. Likewise, statistical comparisons of fetal glyburide AUCs or AUC ratios between gd 15 and 19 were conducted using the same method.

Differences in fetal glyburide concentrations were compared between gd 15 and 19 at each of nine time points (from 0 to 240 minutes) and were evaluated for statistical significance. Because glyburide was quantified in individual fetuses, fetal concentrations derived from the same litter were not considered statistically independent. For that reason, a generalized estimating equation approach was used to account for that dependence. Differences in fetal glyburide concentrations between gd 15 and 19 at each time point (between 0 and 240 minutes) were therefore determined using a generalized estimating equation with an independent correlation structure. The same approach was used to model differences between fetal/maternal glyburide concentration ratios on gd 15 and 19 at each time point. In both cases, the R package geepack (Yan and Fine, 2004; Halekoh et al., 2006) was used to perform the calculations, and calculated $P$ values were adjusted for multiple testing using a Bonferroni correction.

**Results**

**Maternal Glyburide Disposition Changed in a Gestational Age-Dependent Manner.** Wild-type FVB mice of various gestational ages (gd 0, 7.5, 10, 15, and 19) were administered 20 μg glyburide per mouse by retro-orbital injection. As shown in Fig. 1, within each gd group, maternal plasma glyburide concentrations decreased over time from 0 to 240 minutes in a biexponential fashion. As gestation advanced, glyburide concentrations showed a progressive decrease at nearly every time point; the largest differences between gestational ages occurred in the first 60 minutes after dosing. These changes are reflected by decreases in the coefficient of the slow exponential term ($B$) when the bootstrapped plasma concentration data were fit to a biexponential equation. However, distribution ($A$) and elimination ($B$) rate constants remained unchanged during pregnancy (Table 1). All of the derived two-compartmental model parameters for the maternal plasma glyburide PK are shown in Table 1. The $\text{AUC}_{0-240}$ min of glyburide steadily decreased throughout gestation by as much as 50% on gd 15 and 19 compared with nonpregnant controls (20.7, 21.2, and 47.9 μg min mL$^{-1}$ on gd 15, 19, and 0, respectively; $P = 0.001$). Accordingly, glyburide $CL$ increased more than 2-fold on gd 15 and 19 compared with nonpregnant controls (0.97, 0.94, and 0.42 mL min$^{-1}$ on gd 15, 19, and 0, respectively; $P < 0.05$). $CL_{\text{int}}$ estimates also demonstrated a gestational age–dependent increase (approximately 1.5-fold increase on gd 15 and 19 versus gd 0). $V_{ss}$ was unaffected by pregnancy; however, $V_{ss}$ and $V_{ss}$ showed a significant 2-fold increase on gd 10 and nearly tripled on gd 15 and 19 compared with nonpregnant controls. The mean body residence time did not significantly change throughout gestation since the distribution and elimination rate constants did not vary across gestational ages. Maternal plasma protein binding ($f_{\text{u}}$) of glyburide was not significantly affected by pregnancy throughout gestation.

**Maternal Metabolite Exposure Relative to Glyburide Exposure Was Unchanged during Pregnancy.** Primary metabolites of glyburide (M1, M2a, M2b, and M3) were also quantified in all maternal plasma samples collected. As shown in Fig. 2, within each gd group, maternal plasma
TABLE 1

Gestational age-dependent pharmacokinetics of glyburide in maternal plasma using a two-compartmental model

Data are reported as the mean (95% confidence interval) or the mean ± S.D. for data from six maternal plasma samples for each gestation day, with duplicate determinations for each maternal plasma sample. Body weight data are the mean ± S.D. from approximately 30 mice per gestation day.

<sup>#</sup> Estimation of glyburide using a two-compartmental model in gd 0 and gd 7.5; gd 19 did not have statistically significant (P < 0.05) differences versus gd 0.
fetal/maternal plasma AUC$_{0-240}$ min ratio of glyburide doubled from gd 15 to 19 as well (1.8% versus 3.7%, respectively; $P = 0.007$). Fetal concentrations of all four metabolites were below the detection limit for all time points on gd 15 and 19.

**Gestational Age-Dependent Changes in Maternal Glyburide Metabolism.** We hypothesized that increased glyburide CL in pregnant mice versus nonpregnant controls is the result of increased cytochrome P450–mediated metabolism of glyburide in the liver. To test this hypothesis, the glyburide depletion rate was measured in microsomes prepared from maternal livers collected on gd 0, 7.5, 10, 15, and 19. The mean time courses of glyburide depletion during incubation with liver microsomes for the five gestational age groups are shown in Fig. 4A. There was indeed a gestational age–dependent increase in glyburide CL$_{int}$ in the liver, which doubled by gd 19 versus gd 0 (0.17 versus 0.09 ml min$^{-1}$ mg protein$^{-1}$, respectively) (Fig. 4B).

**Discussion**

Previous clinical studies showed that the oral clearance of glyburide increased 2-fold during the third trimester in pregnant women with GDM compared with nonpregnant controls (Hebert et al., 2009). Diagnosis and treatment of GDM most often occur in the second trimester (Metzger et al., 2007). In addition, women who are at risk for developing GDM or have a previous history of GDM may be screened and treated earlier in pregnancy (Metzger et al., 2007). Therefore, it is important to understand glyburide PK changes throughout gestation, as well as how such changes affect glycemic control. In this study, we characterized maternal-fetal glyburide disposition throughout gestation in a pregnant mouse model, since it is not feasible to obtain data at this level of detail in pregnant women.

We found that the maternal plasma PK of glyburide changes in a gestational age–dependent manner, with the largest alterations occurring in mid-late gestation on gd 15 and 19 (Fig. 1; Table 1). In particular, maternal glyburide CL, V$_g$, and V$_{ss}$ steadily increased over gestation and were approximately doubled by mid-late gestation. Glyburide has a low hepatic extraction ratio (approximately 0.1) with no significant renal CL. Therefore, the increase in maternal systemic CL could be accounted for by changes in $f_u$ in plasma and CL$_{int}$ of glyburide in the liver. The $f_u$ did not increase throughout gestation (Table 1), which was somewhat unexpected considering that plasma albumin is known to decrease during pregnancy (Anderson, 2005). However, the $f_u$ of glyburide also did not change in pregnant women with GDM compared with nonpregnant controls (Hebert et al., 2009). The reasons why the $f_u$ was unaffected by pregnancy are not clear. It is possible that glyburide can bind to other lipoproteins in the plasma and/or there are biochemical changes in maternal plasma that have offsetting modulation on plasma protein binding of glyburide. Since the $f_u$ of glyburide in maternal plasma did not significantly change throughout gestation, the increase in maternal glyburide CL and CL$_{int}$ is most likely caused by an increase in hepatic CL$_{int}$. Indeed, the glyburide depletion rate in mouse liver microsomes steadily increased as gestation

Fig. 2. Maternal plasma concentration time profiles of metabolites M1–M3 in wild-type FVB pregnant mice throughout gestation. (A) M1. (B) M2a. (C) M2b. (D) M3. Data from gd 0 (♦), gd 7.5 (□), gd 10 (◆), gd 15 (▲), and gd 19 (○) are shown as the mean ± S.D. (n = 3–5 mice per time point). Nonpregnant mice are referred to as gd 0.

GLY, glyburide.

Parameters on gd 7.5, 10, 15, or 19 with statistically significant (P < 0.05) differences versus gd 0.

Data are reported as the mean (95% confidence interval). The metabolite/glyburide AUC ratios were corrected for differences in the molarity between glyburide (494 g mol<sup>-1</sup>) and metabolites (510 g mol<sup>-1</sup>).
progressed (Fig. 4). Using ketoconazole as a CYP3A inhibitor, we previously showed that glyburide was primarily metabolized by CYP3A in mouse liver (Zhou et al., 2010b). This is consistent with the finding that hepatic CYP3A activity is significantly induced by pregnancy in both humans and mice (Hebert et al., 2008; Zhang et al., 2008). This study further confirmed that hepatic CYP3A activity in pregnant mice is induced in a gestational age–dependent manner. It is not known which mouse CYP3A isoforms are responsible for increased glyburide metabolism during pregnancy as we and others have shown that mRNA levels of Cyp3a16, Cyp3a41, and Cyp3a44 are induced, whereas Cyp3a11, Cyp3a13, and Cyp3a25 genes are downregulated in a gestational age–dependent manner (Zhang et al., 2008; Shuster et al., 2013). Increases in Vss and Vβ most likely reflect increases in total body water and fat content during pregnancy, and further suggest that distribution of glyburide into maternal tissues is increased during pregnancy.

Although the pharmacodynamics and therapeutic window of glyburide have not been well characterized, it is possible that 1.5- to 2-fold increases in glyburide CL (and CLbw) and corresponding decreases in AUC warrant consideration when determining appropriate therapeutic management of glyburide in pregnant women. If our animal data indeed reflect gestational age–dependent changes in maternal glyburide CL and AUC in humans, dosing adjustments may be required as early as the first or second trimester. This would be particularly important for pregnant women treated with glyburide starting in the first or second trimester.

Understanding maternal disposition of primary metabolites of glyburide is also important because some metabolites (e.g., M1 and M2b) are pharmacologically active (Balant et al., 1979; Rydberg et al., 1994). We expected that increased glyburide CL across gestation would lead to either no change or increase in the formation of M1–M3, if they are all derived from pathways that are upregulated; instead, maternal plasma AUCs of each of the measured metabolites decreased progressively, reaching a nadir by gd 15 and a slight reversal by gd 19 (Fig. 2; Table 2).

The AUC of a metabolite represents the balance of its formation and elimination rates. A decrease in metabolite AUC can possibly be explained by an increase in elimination clearance of the metabolite. Accelerated metabolite elimination could be due to increased secondary oxidative metabolism, increased phase II conjugation, and/or increased renal clearance of the metabolites. In humans, M1 undergoes glucuronidation mediated by uridine 5’-diphospho-glucuronosyltransferases (UGTs) and M2b is excreted unchanged in the urine (Naraharisetti et al., 2007). UGT1A1 and UGT1A4 expression is indeed induced during human pregnancy (Feghali and Mattison, 2011); however, mRNA levels of UGTs in pregnant mice are relatively unchanged (Shuster et al., 2013). Mechanisms of renal clearance (i.e., active tubular secretion and/or reabsorption) remain unknown for all glyburide metabolites.

*aStatistically significant (P < 0.05) differences between gd 19 and 15.
in humans and mice. Further investigation is required to elucidate the mechanisms of the putative increase in metabolite elimination.

Another possible explanation for a decrease in metabolite AUC as gestation progresses is that the increase in glyburide CL is due to an increase in normally minor metabolic pathway(s) not represented by the measured metabolites; that is, up-regulation of competing pathway(s) results in a decrease in formation of the measured metabolites. M1, M2a, M2b, M3, M4, and M5 are the primary metabolites of glyburide produced by the human liver, and glyburide is metabolized primarily to M5 by CYP19 in human placenta (Zharikova et al., 2009). It therefore is possible that decreases in concentrations of M1–M3 could be due to increased formation of M4 and/or M5 in the maternal liver and placenta. However, without commercially available standards for M4 and M5, we were unable to quantify gestational age–dependent changes in maternal concentrations of M4 and M5.

Table 2 also presents the metabolite/glyburide AUC ratio, which is governed by the ratio of a given metabolite’s formation clearance to its elimination clearance. It is a quantitative index reflecting either the joint or opposing effects of simultaneous changes in formation and elimination clearances of a primary metabolite. Mean AUC ratios for M1 and M2a were elevated on gd 10 and declined to near the gd 0 values by gd 15 and 19. This suggests that the increase in formation clearance of these two metabolites outpaced the increase in their elimination clearances by gd 10. Moreover, the changes in formation and elimination clearances became comparable as gestation progressed beyond gd 10. For M2b and M3, their AUC ratios declined across all the gestation days studied, suggesting that there was a greater increase in elimination clearance compared with formation clearance.

Fetal exposure to glyburide was <5% of maternal exposure, but was doubled on gd 19 versus gd 15 (Fig. 3; Table 3). This change is consistent with the finding that protein expression of BCRP in mouse placenta on gd 15 is 2 to 3 times greater than that on gd 19 (Wang et al., 2006). Glyburide is a substrate of mouse and human BCRP, which limit the transport of glyburide across the placenta barrier (Gedeon et al., 2006; Zhou et al., 2008; Hemauer et al., 2010). As BCRP protein expression decreases from gd 15 to gd 19, glyburide penetration across the placenta to the fetus increases. P-gp could also contribute to the gestational age–dependent changes in fetal exposure to glyburide because both human and mouse P-gp expression in the placenta decreases as gestation progresses (Mathias et al., 2005; Aleksunes et al., 2008; Zhang et al., 2008). M1–M3 were not detectable in fetal homogenates, suggesting that fetal exposure to these primary metabolites is negligible due to their low concentrations in maternal circulations. Since glyburide is highly bound to plasma proteins with a low volume of distribution, the actual fetal plasma concentrations may be higher than what we observed in fetal homogenates. Indeed, one clinical study showed that the mean ratio of the umbilical cord glyburide concentration at delivery to maternal plasma glyburide concentration was approximately 0.7 (Hebert et al., 2009), indicating that a substantial amount of glyburide can cross the placenta to the fetus. Therefore, although total fetal exposure in human pregnancy is not known, there could be times after drug administration that fetal concentrations are nearly as high as maternal plasma concentrations. Although the current dosage of glyburide is safe for use during pregnancy, dosage increases based on gestational age could raise concerns for fetal safety. In addition, since BCRP expression in human placenta decreases from approximately 28 weeks of gestation onward (Meyer zu Schwabedissen et al., 2006), increased fetal exposure to glyburide in late pregnancy would be expected and may pose a safety concern that conflicts with the consideration to increase glyburide doses during pregnancy for improved maternal efficacy.

In summary, we have demonstrated gestational age–dependent maternal-fetal glyburide PK in pregnant mice. Results of

---

**Fig. 4.** Gestational age–dependent depletion kinetics of glyburide in mouse liver microsomes. (A) Semilogarithmic plot of glyburide depletion over time in mouse liver microsomes. Data from gd 0 (○), gd 7.5 (□), gd 10 (▲), gd 15 (●), and gd 19 (○) are shown as the mean ± S.D. (n = 4–6 livers per gestation day). (B) Gestational age–dependent changes in glyburide CL\textsubscript{int}. Data are the mean ± S.D. (n = 4–6 livers per gestation day). Statistically significant differences between gd 0 and gd 7.5, 10, 15 or 19, as indicated by an asterisk, were determined by the Kruskal–Wallis test followed by the Dunn’s multiple comparison test assuming a significance level of 0.05. Nonpregnant mice are referred to as gd 0.
this study suggest the possible need for increased glyburide dosages even in early pregnancy should the same PK changes occur in humans, and that the pregnant mouse is an appropriate animal model to study glyburide disposition during pregnancy.
