ABSTRACT

Cerebral microembolic signal (MES) is an independent predictor of stroke risk and prognosis. The objective of this study is to assess the effects of apixaban, as a representative of the novel oral anticoagulant class, on a rabbit model of cerebral MES. A clinical transcranial Doppler ultrasound instrument was used to assess MESs in the middle cerebral artery in a 30% FeCl₃-induced carotid arterial thrombosis model in male New Zealand White rabbits. Ascending doses of apixaban were evaluated as monotherapy and in combination with aspirin on both arterial thrombosis and MES. Pharmacokinetic and pharmacodynamic responses were also evaluated. The effective dose for 50% inhibition (ED₅₀) of thrombus formation for monotherapy was 0.04 mg/kg per hour apixaban, i.v. (0.03 μM plasma exposure) for the integrated blood flow, 0.13 mg/kg per hour apixaban (0.10 μM plasma exposure) for thrombus weight, and 0.03 mg/kg per hour apixaban (0.02 μM plasma exposure) for MES. Dual treatment with aspirin (5 mg/kg, PO) and apixaban (0.015 mg/kg per hour, i.v.) resulted in a significant reduction in cerebral MES (P < 0.05) compared with monotherapy with either agent. Pharmacokinetic analysis of apixaban and pharmacodynamic assays using activated partial thromboplastin time (aPTT) and prothrombin time (PT) for apixaban- and arachidonic acid-induced platelet aggregation for aspirin were used to confirm the exposure-response relationships. In summary, our study demonstrates that apixaban in a concentration-dependent manner inhibits both arterial thrombosis and MES, suggesting a potential association between factor Xa (FXa) blockade and the reduction in MES in patients at risk of ischemic stroke.

Abbreviations

AA, Arachidonic acid; aPTT, activated partial thromboplastin time; MCA, middle cerebral artery; MES, microembolic signals; NOACs, novel oral anticoagulants; PRP, platelet-rich plasma; PT, prothrombin time; TCD, transcranial Doppler.

Introduction

Cerebral embolism is a common cause of ischemic stroke. Microembolic signals (MESs) in patients with carotid stenosis, myocardial infarction, atrial fibrillation, and mechanical cardiac valves are often detectable in the cerebral circulation by a transcranial Doppler (TCD; Levi et al., 1997; Purkayastha and Sorond, 2012). Clinical evidence has demonstrated that the presence of MES in the cerebral circulation is an independent predictor of the risk and prognosis of stroke (Gao et al., 2004; Markus et al., 2005) and recurrence in patients with previous stroke or transient ischemic attack (TIA) of presumed arterial origin (Valton et al., 1998). MES was also shown to be a clinically relevant biomarker for assessing the efficacy of antiplatelet agents (e.g., clopidogrel and aspirin) in stroke prevention (Markus et al., 2005; Wong et al., 2010). Despite clinical evidence for the correlation between MES and the risk of ischemic stroke, no animal model has been available to evaluate cerebral microembolism for translational research. Therefore, we recently developed a rabbit model of cerebral MES in the setting of ferric chloride (FeCl₃)-induced carotid arterial thrombosis and demonstrated a reduction of MES in response to clopidogrel and aspirin treatment in this model (Zhou et al., 2016).

In contrast to antiplatelet agents, fewer studies (Al-Atassi et al., 2012; Demir et al., 2015) have been devoted to investigation of the effects of anticoagulants on MES, and the results are inconclusive. Since warfarin and the novel oral anticoagulants (NOACs) are the currently available options for stroke prevention in atrial fibrillation (Lin et al., 2015) and recent phase III clinical studies indicate that NOACs resulted in an overall better efficacy-safety profile than warfarin in patients with nonvalvular atrial fibrillation (Lin et al., 2015; Morais and De Caterina, 2016), we aimed to investigate the effects of apixaban as a representative example for the NOAC class on cerebral MES. Apixaban was selected for this study because its in vitro and in vivo properties have been extensively characterized, along with efficacy assessment in various rabbit models of thrombosis and hemostasis for translational research (Pinto et al., 2007; Wong et al., 2011). Thus, the effects of apixaban on both arterial thrombosis in the carotid artery and MES in the middle cerebral artery (MCA) were monitored simultaneously in the current study, as well as the pharmacokinetic and pharmacodynamic parameters in response to the treatment. Furthermore, since aspirin is used as a standard of care in patients with risk of ischemic stroke, the dual therapy of apixaban with aspirin was also assessed.

Material and Methods

Animals. Studies were conducted in male New Zealand White rabbits weighing 2.4–3.0 kg (obtained from Charles River Canada). All the animal studies were carried out in accordance with the Guide for the Care and Use of Laboratory Animals as adopted and promulgated by the US National Institutes of Health, and were approved by the Institution’s Animal Care and Use Committee of Merck Research Laboratories.

FeCl₃-Induced Carotid Arterial Thrombosis and Cerebral Microembolic Signal Detection. The FeCl₃ injury model was established on the basis of procedures described previously (Marsh Lyle et al., 1998; Wang and Xu, 2005) with modifications to optimize study of MES as part of a terminal procedure in rabbits (Zhou et al., 2016). Briefly, animals were anesthetized with a cocktail (ketamine HCl, 50 mg/kg (Pfizer Inc., New York, New York) and xylazine, 5 mg/kg, i.m. (LLOYD, Inc., Shenandoah, IA), and the left common carotid artery was surgically exposed. A Doppler flow probe (Model 1.5 PRB; Transonic Systems, Ithaca, NY) connected to a flowmeter (Model T403; Transonic Systems) was placed on the surface of the artery and blood flow was continuously measured using a PowerLab 16/35 and LabChart Pro data acquisition system (AD Instruments, Colorado Springs, CO). Thrombosis was induced by applying to the adventitial surface of the vessel two pieces of disc-shaped filter papers (7.4-mm diameter, 0.5-mm thick, one above and one beneath the vessel (Life Technologies/Thermo Fisher Scientific, Grand Island, NY)) saturated with 30%, mass/volume, FeCl₃ (anhydrous 98%; ACROS Organics/Thermo Fisher Scientific, Waltham, MA). A piece of parafilm (Fisher Scientific) was put underneath the vessel to protect the surrounding tissue from injury. The filter papers were applied for 5 minutes followed by washout of the residual FeCl₃ by sterile, warm saline. The carotid blood flow was monitored for 60 minutes from the application of FeCl₃ (as time zero). Integrated carotid blood flow over 60 minutes was measured by area under the curve (AUC) calculated by the trapezoidal rule, and expressed as percent of control blood flow as described previously (Wong et al., 2008b). At the end of study (i.e., 60 minutes after FeCl₃ injury), a section of vessel at the injury site (∼20 mm long) was cut and the thrombus was pushed out using a blunt forceps to a parafilm with a drop of saline. The thrombus was briefly washed in saline (to remove loosely trapped blood) and semidried on a piece of parafilm (to remove residual water). The wet weight of thrombus was measured using a balance with a detection limit of 0.001 mg (Mettler Toledo Excellence Plus XP Series Analytical Balances; Mettler-Toledo, LLC, Columbus, OH). Afterward, the vessel was cut to open/validate complete removal of thrombus.

The SONARA TCD system (Nicolet Natus Neurology Inc., Middleton, WI) was used to continuously monitor blood flow velocity and MES in the ipsilateral MCA. A pulsed-wave 2-MHz probe (OD = 11.3 mm,...
90-mm long, focused at 12–25 mm, customized by MTB Medizintechnik Basler AG (Regensdorf, Switzerland) was fixed by a flexible-arm magnetic-base holder (McMaster-CARR, Princeton, NJ) at the posterior end of zygomatic bone of the rabbits, at an angle of ~80 degrees against the buccal surface. The animal was lying supine on a warm pad during the entire period of the experiment. The proximal segment of the MCA was insonated at a depth between 19 and 22 mm, with gain at 1, power at 43%, scale at 77, sample volume of 5, and detection threshold at 3.0 using a unilateral monitory mode. During continuous monitoring, the blood flow profile and MES (defined as high-intensity transient signals, HITS) were saved, and the frequency of MES was automatically determined using an algorithm designed by the Sonora software (Nicolet Natus Neurology Inc.). The recorded MES was further confirmed by an off-line manual analysis on the basis of the criteria defined by the International Consensus Committee (Consensus Committee, 1995; Ringelstein et al., 1998): 1) a unidirectional and short-lasting (<300 milliseconds) signal with an amplitude >3 dB above background, 2) with a traverse at a prespecified depth, and 3) a typical “snap,” “chirp,” or “moon” audible output.

**Drug Administration.** The structure and compound profiles on selectivity, potency, and pharmacokinetic and pharmacodynamic parameters of apixaban have been extensively investigated and reported previously (Pinto et al., 2007; Wong et al., 2011). The intravenous dosing regimen for apixaban in rabbit essentially followed previous reports (Wong et al., 2008a,b) with the following specification: Apixaban dosing solution was prepared in vehicle (35% hydroxypropyl β-cyclodextrin in 10 mM phosphate buffer, pH 7.0) and dosed using continuous intravenous infusion (starting 60 minutes prior to FeCl3 injury). 2 ml/kg. Our pilot pharmacokinetic study (blood samples at 0, 1, and 2 hours of intravenous dosing) for the use of 0.5 mg/kg per hour, demonstrated that plasma drug exposure for apixaban had achieved a steady-state level during the course of experiment (i.e., between 1 and 2 hours after dosing). For the dose-response study, apixaban (0, 0.015, 0.05, 0.15, and 0.5 mg/kg per hour) was intravenously infused at a volume of 2 ml/kg per hour for 2 hours. Aspirin (cat. no. A2093; Sigma-Aldrich, St. Louis, MO) was dissolved in vehicle (0.5% methyl cellulose) and dosed orally once daily for 3 days (2 ml/kg). Owing to rapid hydrolysis of aspirin in solution in a temperature-dependent manner, the dosing solution was kept at 4°C and dosed within 24 hours of preparation. Rabbits were subjected to FeCl3 injury 1 hour after apixaban infusion, or 2 hours after the last oral dosing of aspirin. For a dual combination study, a partially effective dose of both aspirin (5 mg/kg, p.o., for 3 days) and apixaban (0.015 mg/kg per hour, i.v.) was used to determine the combined efficacy on arterial thrombosis and cerebral MES. The 5-mg/kg aspirin, PO dose was selected on the basis of the dose-dependent results reported previously in the same model (Zhou et al., 2016) and confirmed immediately prior to our combination study using vehicle, 5 and 25 mg/kg aspirin, PO, daily for 3 days (n = 5 each). The results of this study are illustrated in the Supplemental Figs. 1 and 2. As in our previous report (Zhou et al., 2016), partial inhibition by 5 mg/kg aspirin of both arachidonic acid-induced platelet aggregation and serum thromboxane B2 levels and almost complete abolishment by 25 mg/kg aspirin were achieved.

**Pharmacokinetics and Ex Vivo Clotting Time Assays.** Blood samples were collected into sodium citrate (with 3.2% final concentration) Vacutainers (Becton Dickinson, Franklin Lakes, NJ) from either the central ear artery or the carotid artery at terminal bleed. Blood samples were centrifuged at 2000 g for 15 minutes at 4°C for plasma preparation and evaluated for pharmacokinetic and ex vivo clotting time assays.

For pharmacokinetic analysis, the plasma samples and plasma standards and quality controls were assessed by protein precipitation with acetonitrile (10 μl plasma + 300 μl acetonitrile). The supernatant of the plasma samples was treated by liquid chromatography–tandem mass spectrometry (LC-MS/MS) for apixaban using Waters Acquity UPLC system (Waters Corporation, Milford, MA) for liquid chromatography and Applied Biosystems/MSD Sciex API 5500 Q-Trap (Applied Biosystems, Forster City, CA) for mass spectrometry analyses. Specifically, water, 0.1% formic acid was used as mobile phase A solution, and acetonitrile, 0.1% formic acid as mobile phase B solution. Water/acetonitrile/formic acid (80: 20:0.1, v/v/v) was used as autosampler wash 1, followed by acetonitrile/isopropanol/acetone/formic acid (50:40:10:0.5, v/v/v/v) as autosampler wash 2. The MonChrom C18, 100 × 2.0-mm, 3-μm column was used at 50°C. A gradient solution containing 95–5% of mobile phase A solution in combination with 5–95% of mobile phase B solution was used to elute the column.

Ex vivo plasma activated partial thromboplastin time (aPTT) and prothrombin time (PT) were determined by standard methods using Pacific Hemostasis aPTT-XL (Thermo Fisher Scientific) and TriniCLOT PT Excel (Teag, Bray, Ireland) on a KC4 Delta coagulation analyzer (Teag).

**Ex Vivo Platelet Aggregation Assay.** Platelet aggregation studies were performed ex vivo using citrated platelet-rich plasma samples at 0, 1, and 2 hours of intravenous dosing) for the use of 0.5 mg/kg per hour, and plasma drug exposures (A) and pharmacodynamic responses for apixaban intravenous dosing. Plasma drug exposures (A) and pharmacodynamic responses for apixaban intravenous dosing. (B) and aPTT (C) are illustrated. *P < 0.05, **P < 0.01, and ***P < 0.001 versus vehicle.

![Figure 2](https://via.placeholder.com/150)
Platelet aggregation was monitored for 5 minutes at 300, 600, and 900 Paired Jolla, CA) was used for comparison among groups at different doses. Bonferroni post-hoc test in GraphPad Prism (Version 6; GraphPad, La Jolla, CA) was used for comparison among groups at different doses. Paired t test was applied for comparisons between paired groups. ED₅₀, defined as doses for half-maximal effect, was determined by a nonlinear four-parameter dose-response curve fit using GraphPad Prism under the dose ranges described in each figure legend. A dose-related increase in drug exposure was confirmed (Fig. 2A), with 0.01 ± 0.001, 0.03 ± 0.001, 0.1 ± 0.005, and 0.425 ± 0.04 μM for 0.015, 0.05, 0.15, and 0.5-mg/kg-per-hour, i.v. doses of apixaban at 1 hour, respectively, yielding concentrations of 0.01 ± 0.007, 0.02 ± 0.003, 0.091 ± 0.004, and 0.325 ± 0.082 μM, respectively, at 2 hours. The ED₅₀ values were defined as 0.03 μM, 0.10 μM, and 0.02 μM apixaban plasma drug exposure for AUC of integrated blood flow, clot weight reduction, and inhibition of MES, respectively.

Ex vivo PT and aPTT analysis confirmed dose-dependent responses by these two pharmacodynamic markers (Fig. 2, B and C). As illustrated in Fig. 2, PT was increased for 2.2 % (vehicle) to 8.2 % (P < 0.05), 15.3 % (P < 0.01), and 42.1 % (P < 0.001). aPTT increased 0.8 % (P < 0.003), 9.3 % (P < 0.04), 37.8 % (P < 0.01), and 40.2 % (P < 0.001) for 0.015, 0.05, 0.15, and 0.5-mg/kg-per-hour, i.v. doses of apixaban for the 1-hour data point, respectively, versus vehicle (Fig. 2, B and C).

Robust correlations were observed between apixaban plasma drug exposure and inhibition of carotid arterial thrombosis and MES. As illustrated in Fig. 3, the correlation of plasma drug levels with MES is shown in Fig. 3. (A, B) The correlations between drug exposure and efficacy (A) and integrated blood flow and clot weight (B). (C) The correlation of plasma drug levels with MES. (D) The correlation of plasma drug levels and PT/aPTT. Data were analyzed using the GraphPad Prism 6 software.
Effect of Dual Treatment with Aspirin and Apixaban on MES in Rabbit Arterial Thrombosis. To assess the effects of dual combination with aspirin and apixaban on MES, partially effective doses of both, i.e., 5 mg/kg aspirin and 0.015 mg/kg per hour apixaban, were selected according to the monotherapy studies for aspirin as described previously (Zhou et al., 2016) and confirmed again (Supplemental Figs. 1 and 2) and for apixaban (Fig. 1). As illustrated in Fig. 4, only a marginal antithrombotic effect on arterial thrombosis was observed for either aspirin or apixaban alone over vehicle, with 65.1 ± 3.9, 73.8 ± 6.9, (13.3% increase over vehicle), and 69.4 ± 4.7, (6.5% increase) in AUC for the integrated blood flow, or 6.97 ± 0.56, 4.43 ± 0.95 (36.4% reduction), and 6.62 ± 0.97 (5.1% reduction) in thrombus weight (mg) for vehicle (n = 13), aspirin (5 mg/kg, n = 6), and apixaban (0.015 mg/kg per hour, n = 6), respectively. A stronger and significant antithrombotic efficacy was achieved for the dual combination with aspirin and apixaban, with 84.3 ± 2.3 (29.4% increase; n = 5, P < 0.05) on AUC of the integrated blood flow or 1.17 ± 0.65 mg (73.9% reduction; P < 0.01) in thrombus weight.

Mean frequency of MES (Fig. 4D) and animals with MES incidence (Fig. 4E) were found to be significantly lower in the combination therapy group (mean frequency = 0.40 ± 0.24, %

Fig. 4. Effects of vehicle, aspirin (5 mg/kg), apixaban (0.015 mg/kg per hour), and combination of aspirin and apixaban on FeCl₃-induced arterial thrombosis and cerebral MES. Combination treatment (n = 5) with aspirin and apixaban further reduced arterial thrombosis by an enhanced carotid blood flow (A, B) or reduction in clot weight (C) compared with aspirin (5 mg/kg, PO, n = 6) or apixaban (0.015 mg/kg per hour, n = 6) alone. Mean frequency (D) and incidence of MES (E) in ipsilateral MCA was further decreased by combined treatment with aspirin and apixaban. *P < 0.05; **P < 0.01, ***P < 0.001, versus vehicle.
MES (+) = 40%; P < 0.01 versus vehicle] compared with either aspirin [mean frequency = 5.5 ± 1.91, % MES (+) = 83%] or apixaban alone [mean frequency = 3.3 ± 0.61, % MES (+) = 100%].

Pharmacokinetic and pharmacodynamic analyses of the combination of aspirin and apixaban are shown in Fig. 5. Pharmacokinetic analysis demonstrated similar levels of plasma drug exposure for apixaban between apixaban alone and the combination group. As expected, the low levels of drug exposure were not sufficient to trigger the prolongation of both PT and aPTT by apixaban (Fig. 5, B and C). In contrast, the ex vivo platelet aggregation assays confirmed the effects of aspirin in either group of aspirin alone or its combination with apixaban, showing significant but only a partial inhibition of the maximum platelet aggregation induced by AA (100, 300, 600, 900 μM) compared with vehicle treatment (P < 0.05, Fig. 5D).

Discussion

Our current study provided direct evidence for the first time that apixaban dose dependently inhibited cerebral MES in the rabbit model of MES in a setting of carotid arterial thrombosis (Fig. 1). Furthermore, this effect was additive with aspirin (Fig. 4). In our current preclinical model, a similar dose response was observed for apixaban in MES and arterial thrombosis, showing the ED_{50} of 0.03 mg/kg per hour apixaban and 0.04 mg/kg per hour for MES and integrated blood flow, respectively. Pharmacokinetic and pharmacodynamic analyses demonstrated an excellent correlation between apixaban plasma drug exposure and efficacy (both thrombus formation and MES) and PT/aPTT.

Improved efficacy-safety profiles compared with warfarin of apixaban and other NOACs has been demonstrated recently in patients with nonvalvular atrial fibrillation in phase III clinical studies (Granger et al., 2011; Lin et al., 2015; Morais and De Caterina, 2016). The use of apixaban to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation was approved by the US Food and Drug Administration in 2012.

Clinical evidence suggests that MES in the cerebral circulation might be an independent predictor of the risk and prognosis of stroke (Gao et al., 2004; Markus et al., 2005), and the propensity toward early ischemic recurrence of stroke in patients with a prior event or TIA of presumed arterial origin (Valton et al., 1998). In addition, MES was shown to be a valuable biomarker in response to treatment with aspirin and clopidogrel, in particular when dosed as combination therapy (Markus et al., 2005; Wong et al., 2010). In our previous study, dose-dependent inhibition of cerebral MES was demonstrated for both aspirin and clopidogrel, in particular with their combination, in the same model of cerebral MES in rabbits (Zhou et al., 2016). MES in this preclinical model were observed in the setting of carotid arterial thrombosis, which mimics the arterial origin of MES as one of the primary sources in patients (Bonati et al., 2010; Yavin et al., 2011). In addition, the relatively low frequency of MES in this preclinical model is similar to what has been observed in patients. Because of the low MES number, however, it might be difficult to accurately define a dose-dependent cure. Thus, one must be cautious in interpreting the ED_{50} data for apixaban on MES. Furthermore, it would be more clinically relevant if MES was derived from atrial fibrillation when considering stroke prevention in atrial fibrillation as the clinical indication. Unfortunately, no preclinical model is available for consistent generation of thrombus or MES in atrial fibrillation setting (Nishida et al., 2012).

It should be pointed out that some limitations exist for the current animal model. First, since the clinical TCD is designed specifically for assessment of MES in patients (such as the software for MES identification and the threshold limit for

Fig. 5. Pharmacokinetic and pharmacodynamic responses for the dual combination study with aspirin and apixaban. Plasma samples from animals of each experimental group were prepared as illustrated in Fig. 4 prior to, or 1 (time of FeCl3 injury) and 2 hours after, 0.015 mg/kg per hour apixaban intravenous dosing. Plasma drug exposures (A) and pharmacodynamic responses shown as PT (B) and aPTT (C) are illustrated (except for the aspirin only group). Ex vivo analysis using arachidonic acid (100, 300, 600, and 900 μM)-induced maximum platelet aggregation (D) confirmed aspirin treatment in both aspirin alone and cotreatment with apixaban and aspirin (apixaban alone not shown). *P < 0.05, versus vehicle.
Apixaban Inhibits Cerebral Microembolic Signals

MES detection), thrombi less than 100 μM in diameter could not be detected. Therefore, it is unknown to what extent the frequency of smaller MES might be affected by apixaban in the current model. Second, the 30% FeCl₂-induced carotid arterial thrombosis was optimized for MES detection in MCA rather than arterial thrombosis (Zhou et al., 2016). Thus, the evaluation of antithrombotic efficacy for therapeutic agents should be carefully correlated clinically. Third, the mechanisms of MES derived from FeCl₂-induced thrombosis remain to be further explored. By means of an in vitro endothelialized microfluidic system, Ciciliano et al. (2015) demonstrated a two-phase mechanisms for FeCl₂-induced thrombus formation, i.e., the initial phase with binding of negatively charged blood cells and plasma proteins to positively charged iron species, followed by the second phase depending on the standard biologic clotting cascade, suggesting that antithrombotic agents might only be effective in the second phase of thrombus formation induced by FeCl₂. Thus, one must interpret the data with caution for the use of FeCl₂ injury model.

Of note, the ED₅₀ for apixaban was defined as 0.04 and 0.13 mg/kg per hour (or 30 and 100 nM) for the integrated blood flow and thrombus weight, respectively, and 0.03 mg/kg per hour (20 nM) for MES (Fig. 1). The reason for ~3-fold difference on the antithrombotic efficacy between the blood flow and clot weight readouts is unknown. The antithrombotic efficacy of apixaban has been previously reported in various rabbit models of thrombosis, including arterial-venous shunt thrombosis, deep vein thrombosis, and electrically induced carotid artery thrombosis, in which the ED₅₀ was defined as 0.27 mg/kg per hour, i.e. (or 370 nM plasma drug level), 0.11 mg/kg per hour, i.e. (65 nM), and 0.07 mg/kg per hour, i.e. (110 nM), respectively (Wong et al., 2008a, 2009). Our current ED₅₀ data for apixaban on arterial thrombosis are in agreement with those previous reports in rabbits and are around a clinical range of peak (174 nM) and trough (37 nM) for apixaban (Frost et al., 2014).

In our previous study, the ED₅₀ for aspirin was defined as 3.1, 4.2, and 12.7 mg/kg for integrated blood flow, thrombus weight, and MES, respectively, and the ED₅₀ for clopidogrel was 0.30, 0.28, and 0.25 mg/kg for integrated blood flow, thrombus weight, and MES, respectively, using the same rabbit model of MES (Zhou et al., 2016). No direct comparison could be made for the antithrombotic effects of aspirin in rabbits with others (owing to the use of different dosing regimens). Since the dose of aspirin in the current rabbit model appeared to be less potent than those used in patients (Markus et al., 2005; Wong et al., 2010), we conducted a head-to-head comparison using both human and rabbit PRPs for AA-induced platelet aggregation assays in response to various concentrations of aspirin (Supplemental Fig. 3). This in vitro platelet aggregation study suggests that aspirin might be more sensitive (~10–100×) in human PRP than in rabbit. Since rabbit platelets appear to be resistant to aspirin, the rabbit model might not be the best one to assess efficacy and/or safety for the aspirin and apixaban drug combination. In contrast to aspirin, the ED₅₀ value for clopidogrel on arterial thrombosis appeared to be more potent (about 3-fold) than those from a rabbit model of electrically induced carotid artery thrombosis (ED₅₀ = 0.8 mg/kg/d, PO) (Wong et al., 2008b).

In summary, our study demonstrated the dose-dependent inhibition of MES by apixaban, which could be further enhanced when apixaban is dosed in combination with aspirin. Our data provided direct evidence for the potential association between FXa blockade and MES in the preclinical experimental model.

Acknowledgments

The authors thank Richard Kennan for helpful discussions, Stan Kurowski and Michael Wismer for technical supports on initial model set up, the authors’ colleagues in analytical group for apixaban plasma drug analysis, and Animal Resources Staff for their help with oral dosing and animal care.
