Non-standard abbreviations:

AM4054: 9β-(hydroxymethyl)-3-(1-adamantyl)-hexahydrocannabinol
AM4113: 5-(4-alkylphenyl)-1-(2,4-dichlorophenyl)-4-methyl-N-(piperidin-1-yl)-1H-pyrazole-3-carboxamide
AM411: (6aR,10aR)-3-(1-adamantyl)-6,6,9-trimethyl-6a,7,10,10a-tetrahydrobenzo[c]chromen-1-ol
SR141716A: 5-(4-chlorophenyl)-1-(2,4-dichloro-phenyl)-4-methyl-N-(piperidin-1-yl)-1H-pyrazole-3-carboxamide
R-(-)-NPA: (6aR)-5,6,6a,7-tetrahydro-6-propyl-4H-dibenzo[de,g]quinoline-10,11-diol
SCH 23390: (R)-(+) -7-chloro-8-hydroxy-3-methyl-1-phenyl-2,3,4,5-tetrahydro-1H-3-benzazepine hydrochloride
SKF 82958: (±)-6-Chloro-7,8-dihydroxy-3-allyl-1-phenyl-2,3,4,5-tetrahydro-1H-3-benzazepine hydrobromide
Δ⁹-THC: Δ⁹-tetrahydrocannabinol
WIN 55,212: R-(+)-[2,3-dihydro-5-methyl-3-[(morpholinyl)methyl]pyrrolo[1,2,3-de]-1,4-benzoxazinyl]-(1-naphthalenyl)methanone mesylate
ABSTRACT

Behavioral studies of chronic CB₁ receptor activation may provide a pharmacological approach to understanding efficacy-related differences among CB₁ ligands and, as well, mechanistic commonalities between cannabinoid and non-cannabinoid drugs. In the present studies, the effects of CB₁ agonists (AM411, AM4054, WIN55,212.2, Δ⁹-THC, methanandamide), CB₁ antagonists (SR141716A, AM4113), and of dopamine (DA)-related [methamphetamine, SKF82958, SCH23390, R-(-)-NPA, haloperidol] and opioid (morphine, naltrexone) drugs on scheduled-controlled responding under a 30-response fixed-ratio (FR30) schedule of stimulus-shock termination in squirrel monkeys were compared before and during chronic treatment with the long-acting CB₁ agonist AM411 (1.0 mg/kg/day, i.m.). Pre-chronic treatment with all drugs except naltrexone (1–10 mg/kg) produced dose-related decreases in responses rates. Dose-response re-determinations during chronic treatment revealed: a) >250 fold (AM411, methanandamide) and >45-fold (AM4054, WIN55,212.2, Δ⁹-THC) rightward shifts in the ED₅₀ values for CB₁ agonists; b) >100-fold and >20-fold leftward shifts in the ED₅₀ values for SR141716A and AM4113, respectively; and c) approximately 4.8- and 10-fold rightward shifts in the ED₅₀ values for methamphetamine and the DA D₂ agonist R-(-)-NPA, respectively. Dose-response relationships for other DA-related and opioid drugs were unchanged by chronic CB₁ agonist treatment. Differences in the magnitude of tolerance among CB₁ agonists during chronic treatment may be indicative of differences in their pharmacological efficacy, whereas the enhanced sensitivity to behaviorally disruptive effects of CB₁ antagonists may provide evidence for CB₁-related behavioral and/or physical dependence. Finally, the development of cross-tolerance to methamphetamine and R-(-)-NPA bolsters previous evidence of interplay between CB₁ and DA D₂ signaling mechanisms.
INTRODUCTION

The frequent use of CB₁ receptor agonists may lead to pharmacological tolerance and dependence, especially in view of the long-lasting effects of commonly-used drugs such as Δ⁹-THC in marijuana and marinol or, more recently, synthetic cannabinoids such as JWH-018 or JWH-073 in K2 and Spice (Atwood et al., 2011; Benford and Caplan, 2011; Panagis et al., 2008). However, tolerance does not appear to develop uniformly across studies or ligands. Thus, rapid (within 3–7 days) tolerance may occur to some effects (e.g. antinociception) of Δ⁹-THC and other CB₁ agonists in rodents; however, sensitivity to other effects (e.g., memory impairment) remains unaltered—even after weeks of chronic treatment with large doses of CB₁ agonists (Panagis et al., 2008). Furthermore, cross-tolerance among CB₁ agonists, e.g., Δ⁹-THC and the endogenous CB₁ ligand, anandamide or its analogues, is not consistent across assay endpoints, i.e., evident in studies of antinociception but not in studies of hypothermia or the disruption of operant behavior (reviewed in Panagis et al., 2008; Singh et al., 2011). Based on current understanding, differential tolerance across CB₁-related endpoints may reflect regional differences in CB₁ receptor down regulation/desensitization in the CNS, whereas differential cross-tolerance across CB₁ ligands may reflect differences in pharmacological efficacy (Panagis et al., 2008; McMahon, 2011).

Recent studies in human subjects and laboratory animals suggest that frequent exposure to CB₁ agonists also leads to physical dependence (e.g., Haney et al., 1999; Budney et al., 2004; Panagis et al., 2008). Classical physical dependence may be defined by physiologic adaptation to effects of a drug that subsequently necessitates the presence of the drug for normative function (Alford et al., 2006). Physical dependence is identified by the appearance of an abstinence
syndrome following either discontinuation of chronic drug treatment (spontaneous withdrawal) or administration of a receptor antagonist during chronic treatment (antagonist-precipitated withdrawal). Disturbed sleep is a recognized effect of discontinuing Δ⁹-THC in man, but prominent signs of a CB₁-related abstinence syndrome have been difficult to identify in laboratory animals (Budney et al., 2004; Panagis et al., 2008). Early studies with Δ⁹-THC by Beardsley et al. (1986) provided evidence for behavioral dependence (i.e., the disruption of learned behavior by discontinuation of chronic treatment) in nonhuman primates; however, the relationship between behavioral dependence and physical dependence was not clarified. Other studies in chronically-treated monkeys have suggested that relatively small changes in overt and operant behavior following abrupt discontinuation may be indicative of a Δ⁹-THC-induced abstinence syndrome (Fredericks and Benowitz, 1980; Stewart and McMahon, 2010). Possibly, the relatively slow clearance of Δ⁹-THC following discontinuation prevents a full expression of signs of withdrawal—similar to the limited withdrawal observed following discontinuation of long-acting benzodiazepines or gradual dose reduction of chronically-administered opioids (e.g., Landry et al., 1992; Bergman and Schuster, 1985).

The development of CB₁ antagonists such as rimonabant (SR141716A) has enabled studies of antagonist-precipitated cannabinoid withdrawal, as previously done with naltrexone in opioid-dependent subjects (e.g., Gellert and Holtzman, 1979; Woods et al., 1982). For example, i.v. doses of 0.32–1.0 mg/kg of rimonabant recently were shown to produce discriminative-stimulus or rate-decreasing effects in monkeys that were chronically treated with Δ⁹-THC, whereas a dose of 3.2 mg/kg was required to produce behavioral effects in untreated subjects (Stewart and McMahon, 2010; McMahon 2006, 2011). Such findings encourage the idea that antagonist-precipitated withdrawal may be a useful means for studying CB₁ dependence.
In the present work, CB₁-related tolerance and dependence was further characterized by evaluating changes in sensitivity to effects of CB₁ receptor agonists and antagonists on schedule-controlled behavior, a reliable and sensitive assay for studying cannabinoid tolerance and dependence (Beardsley et al., 1986; McMahon, 2011). Subjects were treated daily with the CB₁ agonist AM411, a recently-developed and long-acting adamantyl analog of Δ⁸-THC (Lu et al., 2005), using doses that disrupt operant behavior for 24-48 hrs when given acutely (0.3-1.0 mg/kg; Delatte et al., submitted). Next, changes in sensitivity to effects of AM411 and other CB₁ receptor agonists and antagonists during chronic treatment were studied by analyzing dose-response functions for rightward (tolerance) or leftward (sensitization) movement. Based on reported interactions with dopaminergic and opioid systems (Maldonado, 2002; Tanda and Goldberg, 2003), similar evaluations were conducted with selected monoaminergic and opioid drugs. Overall, the present results show: 1) differential magnitudes of tolerance among CB₁ agonists that may be related to efficacy at CB₁ receptors; 2) enhanced sensitivity to behaviorally disruptive effects of CB₁ antagonists; and 3) cross-tolerance to effects of methamphetamine and the D₂ receptor agonist R-(-)-NPA. These data provide further evidence for CB₁-related behavioral and/or physical dependence and strengthen previous findings of interplay between CB₁ and DA D₂ signaling mechanisms.
METHODS

Subjects.

Experimentally naïve adult male squirrel monkeys (Saimiri sciureus; n = 4), weighing 650 to 900 g were individually housed in stainless steel cages in a temperature and humidity controlled vivarium under a 12-h light/dark cycle. All monkeys had unlimited access to water (except during the test session) and were fed a daily allotment of high protein monkey chow (Purina Monkey Chow, St. Louis, MO), supplemented with fruit and multivitamins, in the home cage. Behavioral testing was conducted between 08:00 AM and 06:00 PM, under protocols that were approved by the Institutional Animal Care and Use Committee at McLean Hospital. This facility is licensed by the U.S. Department of Agriculture. Subjects were maintained in accordance with guidelines provided by the Committee on Care and Use of Laboratory Animals of the Institute of Laboratory Animals Resources, National Institutes of Health.

Apparatus.

During experimental sessions, subjects sat in customized Plexiglas chairs (based on Kelleher and Morse, 1968) in ventilated chambers that were provided with white noise to mask extraneous sounds. While seated, monkeys faced a panel containing colored stimulus lights that could be illuminated to serve as visual stimuli and a response lever that protruded through the front panel of the chair and was easily accessible to the subject. Each lever-press with a force > 0.2 N produced an audible click and was recorded as a response. A shaved portion of the seated monkey’s tail was comfortably secured under brass electrodes by a small stock and was coated with electrode paste to ensure a low-resistance electrical contact between electrodes and tail. Brief, low-intensity current (200 msec; 3 mA) could be programmed for delivery to the tail from
a 50 Hz transformer. Stimulus events were programmed and data was recorded using a commercially available interface and computer program (MED-PC, MedState Notation, Med Associates Inc., St. Albans, VT, USA).

Behavioral Procedure.

Subjects responded under a 30-response fixed-ratio (FR30) schedule of stimulus-shock termination (Morse and Kelleher, 1966; Bergman et al., 1995). Under terminal contingencies, daily sessions began with illumination of the visual stimuli on the front panel of the chair; current was scheduled for delivery to the monkey’s tail every 20-sec during the time that stimulus lights were illuminated. Under this schedule, the completion of 30 consecutive responses within the 20-sec interval extinguished stimulus lights and the associated program of current delivery, and initiated a 10-sec timeout (TO) period during which all lights in the chamber were off and lever-presses had no scheduled consequences. After the 10-sec TO, the visual stimuli were re-illuminated and the schedule contingencies were again in effect. Daily sessions comprised five successive components. Each component consisted of a 10-min TO period during which no stimuli were presented and lever-press responses had no scheduled consequences followed by a 3-min response period during which the FR30, TO10 schedule of stimulus-shock termination was in effect. Under these conditions, each component terminated after the 3-min response period or the fourth delivery of current to the monkey’s tail, whichever occurred first.
Drugs.

CB₁ ligands, except Δ⁹-THC and rimonabant, were synthesized at the Center for Drug Discovery (Northeastern University, Boston, MA). These included the novel CB₁ agonists AM411 (Lu et al., 2005) and AM4054 (Delatte et al., 2008; Thakur and Makriyannis, in preparation), the stable analog of the endocannabinoid anandamide, methanandamide (AM356), and the CB₁ neutral antagonist AM4113 (Bergman et al., 2008; Sink et al., 2008). The CB₁ agonist Δ⁹-THC and the inverse agonist/antagonist rimonabant (SR141716A) were obtained from the National Institute of Drug Abuse (Bethesda, MD). WIN55,212.2, methamphetamine, SKF82958, SCH23390, R-(−)-NPA, haloperidol, morphine, and naltrexone were obtained from Sigma-Aldrich (St. Louis, MO). Vehicles were either 0.9% saline (methamphetamine, morphine, naltrexone, R-(−)-NPA, SCH23390, SKF82958) or a 20:60:20 mixture of emulphor (Alkamuls EL-620; Rhone-Poulenc, Cranbury, N.J., USA), 0.9% saline, and 95% ethanol (AM411, AM4054, methanandamide, AM4113, Δ⁹-THC, rimonabant, haloperidol, WIN55,212.2). With the exception of CB₁ antagonists, all drug solutions were injected i.m. (calf or thigh muscle) in volumes ranging from 0.2 to 0.4 ml/kg body weight; control injections were similar volumes of drug vehicles. The effects of the two CB₁ antagonists, rimonabant and AM4113, were studied during sessions that follow intravenous (i.v.) injections via the tail vein.

Drug Testing.

Drug studies were initiated after stable responding was achieved in all subjects. Stable responding was defined by less than 10% variability in overall response rates during the session over ten successive sessions. Typically, test sessions were conducted once or twice per week (Tuesdays and/or Fridays), and training sessions were conducted on intervening days. During
test sessions all schedule parameters and contingencies were identical to those in the training sessions, with the exceptions that 1) the program of current delivery was not in effect and 2) either 30 consecutive lever responses or the passage of 20 sec resulted in the termination of stimulus lights and followed by a short timeout period. Whenever possible, full dose-response functions for each drug were established in all subjects by determining the effects of a range of doses up to those that decreased response rates to below 50% of control values. The effects of CB₁ agonists and antagonists were determined using single-dosing procedures, whereas the effects of all other drugs were determined using cumulative-dosing procedures previously employed in our laboratory (e.g., Bergman and Spealman, 1988). Briefly, under single dosing procedures, a dose of the test drug was administered prior to the start of the first component, and injections of saline (approx. 0.3 ml) were administered at the beginning of each subsequent component of the test session. Under cumulative dosing procedures, graded doses of the drug were administered i.m. at the beginning of sequential components of the test session, i.e., at the onset of the 10 min timeout periods that initiated session components. The latter procedure allowed for determination of up to five cumulative doses in a single test session; overlapping ranges of cumulative doses were administered in separate test sessions when necessary to determine the effects of more than five drug doses. Test sessions always were preceded by either vehicle- or noninjection-training sessions in which the subject consistently terminated visual stimuli and the program of current delivery within the 20-sec limited hold throughout the five components of the daily session with response rates that were within control values (3 – 4 responses per sec across monkeys. Experiments with one drug were generally completed prior to determining the effects of another drug, and drugs were tested in an irregular order among subjects. For cannabinoids, doses of each drug also were studied in an irregular order in
individual subjects using single dosing procedures described above. Based on the results of preliminary experiments, AM411 was studied by administering single i.m. doses 90 min pre-session whereas other CB₁ agonists including AM4054, methanandamide, Δ⁹-THC, and WIN55,212.2 were administered i.m. 30-min prior to the session. CB₁ receptor antagonists including the inverse agonist/antagonist, SR141716A and the neutral antagonist AM4113 were studied by administering i.v. doses 10 min pre-session. The effects of all non-cannabinoid drugs were determined using cumulative dosing procedures described above.

Upon completion of pre-chronic studies, chronic treatment with the CB₁ receptor full agonist AM411 began with daily i.m. injections 90 min prior to the session. Injections were given between 10:00 a.m. and 2:00 p.m on weekend days when behavioral sessions were not conducted. The daily dosage of AM411 was selected on the basis of pre-chronic dose-response data; treatment began with a single i.m. injection of 0.32 mg/kg/day. After four days, the daily dosage was increased to 1.0 mg/kg, where it remained for the rest of the chronic regimen (460 days). After tolerance to the behaviorally disruptive effects of 1.0 mg/kg AM411 was evident (see Results) and stable baseline performance was regained, dose-response functions for all drugs were re-determined in each subject, using injection procedures described above. On test days, pre-session injections of AM411 were suspended and, instead, the chronic dosage of AM411 was administered when the subject was returned to the vivarium following the test session. After the effects of all drugs were re-determined during the chronic regimen, the dosage of AM411 was reduced to 0.32 mg/kg/day for approximately 7 days before terminating daily drug injections. This was done as a precaution to minimize untoward effects that might have resulted from more abrupt discontinuation of chronic treatment with AM411.
Data Analysis.

Rates of responding under the FR30 stimulus-shock termination schedule were calculated separately in each component of the session by dividing the total number of responses during the time stimulus lights were illuminated by the total time of illumination. Mean control rates of responding in each component were calculated by averaging data from all training session that immediately preceded drug test sessions. The effects of each treatment administered as a single injection were calculated by averaging data across all components and expressing the mean value as a percentage of the mean control rate of responding throughout the session. The effect of each cumulative dose was calculated as a percentage of the mean control response rate during the session component in which it was administered.

Data from drug testing sessions were calculated for each subject and averaged for the group of monkeys to provide mean (± S.E.M.) values for the construction of dose-response functions for each drug during pre-chronic and chronic phases of study. When appropriate, averaged dose-effect data were analyzed using standard linear regression techniques using Bioassay® software (MED Associates Inc., Bioassay Version: Beta 6.2). ED$_{50}$ values and their 95% confidence limits were determined from points on the linear portions of the dose-response functions (Snedecor and Cochran, 1967). ED$_{50}$ values from pre-chronic and chronic dose-effect curves were compared for each drug, and were considered to be significantly different if their 95% confidence limits did not overlap. The magnitude of shifts that occurred in dose-response functions are expressed in terms of relative potency estimates that were calculated by standard parallel-line bioassay techniques described in Finney (1964). Briefly, when slopes do not significantly deviate from parallelism, a significant difference between two dose-response functions is indicated when the 95% confidence limits for the relative potency ratio do not
include the value 1.0. Time course data shown in Figure 1 were analyzed using a repeated-measures analysis of variance (ANOVA) followed by Bonferroni’s t-test for post-hoc analysis. In all cases, significance was defined at the 95% level of confidence (\( p < 0.05 \)).
RESULTS

Control Performance. Under control conditions, subjects reliably terminated visual stimuli and the program of current delivery within 20-sec after illumination throughout the five components of the daily session. Stable control rates and patterns of responding were evident across all five successive components of the session throughout the present studies and, averaged for the group of monkeys, ranged from 3.22 (±0.07) – 4.40 (±0.09) responses per sec. Injections of vehicle had no systematic effect on responding in individual subjects and, control rates of responding also did not vary significantly across injection procedures (i.e., pretreatment time: 10, 30, 60, 90 min; route of administration: i.m. or i.v.; session: vehicle or non-vehicle); hence, mean overall values (±S.E.M.) were obtained by averaging response rates from all control sessions during the three phases of study, i.e., before, during, and after discontinuation of chronic exposure to AM411 (18–26 control sessions per condition). Mean control rates of responding exhibited an upward trend over the course of the present studies but did not differ significantly across the three phases of study (3.53±0.08, 4.08±0.12, and 4.40±0.09 responses per sec before, during, and following chronic treatment with AM411).

Figure 1 shows the effects of the AM411 in squirrel monkeys responding under a FR30 schedule of stimulus-shock termination before and during chronic treatment with i.m. 1.0 mg/kg/day AM411. (Note that, as marked changes in the effects of AM411 across sessions were not evident, data averaged for the group of monkeys from Day 20 to Day 480 were plotted in increments of 20 sessions.) On the first day of chronic treatment, 0.32 mg/kg AM411 reduced FR responding to approximately 60% of previous control values, an effect that dissipated over the next four sessions (Fig. 1). Subsequently, the daily i.m. treatment dose of AM411 was increased to 1.0 mg/kg/day, which decreased response rates to approximately 80% of previous
control values (Fig. 1). This slight depression of response rate was still evident after 7–10 of
treatment and slowly dissipated through the first half of the chronic regimen (~ 220 days; Fig. 1). Thereafter, from days 220 – 460, response rates slightly increased to approximately 110 – 120 % of previous control values and remained at that level for the remainder of the chronic treatment regimen. A repeated measures ANOVA confirms a significant effect of treatment \[F(37,111) = 7.61; p < 0.001\] prior to chronic treatment, i.e., post-hoc analysis (Bonferroni’s ‘t’-test) revealed a significant difference between control response rates and response rates following 0.32 and 1.0 mg/kg AM411 \((p \text{ values} < 0.001)\). However, the effects of 0.32 and 1.0 mg/kg AM411 on response rates no longer differed significantly from control values during chronic treatment, \((p \text{ values} > 0.05)\).

**Effects of CB1 Receptor Agonists.** The effects of AM411 before and during chronic exposure are compared for the group of subjects in Figure 2. Prior to chronic treatment, AM411 (0.01 – 1.0 mg/kg, i.m.) decreased response rates in a dose-related manner, to 20% of control values following the highest dose (1.0 mg/kg) (Fig. 2). The group ED50 value, i.e., the dose of AM 411 calculated to decrease response rates to 50% of control values, was 0.26 mg/kg \((95\%\text{CL}: 0.08-5.24; \text{Table 1})\). Following chronic treatment, a profound tolerance to the rate-decreasing effects of AM411 was observed in all monkeys; the highest i.m. doses of AM411 that could be administered (100 mg/kg) failed to produce >35% decreases in FR responding, precluding the determination of a mean ED50 value (Fig. 2).

The effects of other CB1 receptor agonists before and during chronic treatment with AM411 are shown in Figure 3. Like AM411, pre-chronic administration of AM4054 (0.0032 – 0.1 mg/kg), WIN55,212.2 (0.01 – 1.0 mg/kg), \(\Delta^9\)-THC (0.032 – 3.2 mg/kg), and
methanandamide (1.0 – 10 mg/kg) produced dose-dependent decreases in rates of FR responding. Following the highest dose of each CB₁ agonist, overall response rates decreased to ≤30% of control values. Based on ED₅₀ values (Table 1), the rank order of potencies with which the CB₁ agonists decreased response rates prior to chronic treatment with AM411 were: AM4054 > AM411 > WIN55,212.2 > Δ⁹-THC > methanandamide (note: ED₅₀ values for methanandamide were not determined due to nonsignificant regression; however, behaviorally effective doses were higher than those of other drugs). Chronic daily treatment with AM411 resulted in a >1.5 log unit rightward shift in the dose-response function for each CB₁ agonist (Fig. 3). As in prechronic determinations, the highest doses of AM4054 (3.2 mg/kg), WIN55,212.2 (32 mg/kg), and Δ⁹-THC (100 mg/kg) decreased overall rates of FR responding to <50% of control values, and their rank order of potency was unchanged: AM4054 > WIN55,212.2 > Δ⁹-THC (Fig. 3; top and bottom left panels, respectively and Table 1). Relative potency estimates confirm the significant differences observed between the dose-effect functions for each CB₁ agonist determined before and during chronic treatment (Table 1). As with AM411, the highest doses of methanandamide (100–320 mg/kg, i.m.) failed to produce >25% decreases in rates of FR responding (Fig. 3; bottom right panel), precluding the determination of ED₅₀ values during the chronic regimen. Studies with higher doses of AM411 and methanandamide during the chronic AM411 regimen were not possible due to limitations in drug solubility.

The effects of AM4054 also were re-determined immediately prior to the conclusion of the chronic regimen to determine whether further changes in CB₁ sensitivity might have occurred. In these last determinations, AM4054 continued to produce dose-dependent decreases
in rates of FR responding, and overall response rates decreased to <50% of control values for the group of subjects following the highest dose of AM4054 (3.2 mg/kg; Fig, 3; top left panel).

**Effects of Cannabinoid CB1 Receptor Antagonists.** Prechronic administration of both rimonabant (3.2 – 18 mg/kg, i.v.), and AM4113 (1-10 mg/kg, i.v.) produced dose-related decreases in overall response rates, and, following the highest doses, decreased responding to approximately 20–30% of control rates of responding (Fig. 4). During chronic treatment with AM411, the dose-related effects of both drugs were markedly enhanced, as evident in the >2–fold and 1-1.5–fold log unit leftward shifts in the dose-effect functions for, respectively, SR141716A and AM4113 and, also, the corresponding decreases in their ED$_{50}$ values (Fig. 4; Table 1). All subjects were observed for signs of motoric impairment and easily-identifiable changes in home cage behaviors (e.g., grooming, affiliation, vocalization) following doses of SR141716A and AM4113 that significantly disrupted rates of responding. Excepting profuse salivation, easily-identifiable or consistent effects on overt behavior that might be indicative of physical dependence (Panagis et al., 2008) were not observed following rate-decreasing doses of the two drugs.

**Effects of DA-related agonists and antagonists.** Interactions between cannabinoid and DA systems were examined by comparing the effects of the indirect DA agonist, methamphetamine, the DA D$_1$- and D$_2$-like agonists (SKF82958 and R-(−)-NPA, respectively) and the D$_1$- and D$_2$-like antagonists (SCH23390 and haloperidol, respectively) on FR response rates before and during the chronic regimen. Prior to chronic treatment, all drugs produced dose-related reductions in responding, with substantive (>75%) decreases in overall response rates following the highest dose of each DA agonist or antagonist (Figs. 5, 6; Table 2). Chronic treatment with
AM411 led to significant changes in potency for some but not all DA-related drugs. Thus, 0.5–1.0 log unit rightward shifts in dose-effect functions, with corresponding and significant increases in ED₅₀ values, were evident for methamphetamine and the D₂-like agonist R-(-)-NPA (Fig. 5; Table 1). However, the position of the dose-response function for the D₁-like agonist SKF82958 and its ED₅₀ value were unchanged by chronic treatment with AM411 (Fig. 6). Similarly, despite some attenuation of the rate-decreasing effects of the highest doses of SCH23390 (0.032 mg/kg) and haloperidol (0.32 mg/kg) the dose-response functions and, correspondingly, ED₅₀ values for the D₁ and D₂ receptor antagonists were not significantly altered by chronic AM411 treatment (Table 2).

*Effects of morphine and naltrexone.* As shown in Fig. 6 and Table 2, no evidence for significant cross-tolerance or sensitization was obtained with either the µ opioid agonist morphine or the non-selective opioid antagonist naltrexone in the present experiments. Prior to chronic treatment, morphine (0.032 – 3.2 mg/kg; i.m.) produced a dose-dependent reduction in response rates, with the highest dose, 3.2 mg/kg, decreasing responding to <20% of control values (Fig. 6; right panel). Although a slight rightward shift in the dose-response function occurred during chronic AM411 exposure (Fig. 6; right panel), inspection of ED₅₀ values and relative potency analysis of the pre-chronic and chronic dose-response functions indicate no significant change in morphine sensitivity (Table 1). Similarly, no change in sensitivity to naltrexone (1.0 – 10 mg/kg; i.m.) was apparent; the opioid antagonist failed to significantly alter FR response rates prior to or during chronic AM411 exposure (Table 1).
DISCUSSION

In the present study, chronic treatment with AM411, a long-acting CB₁ receptor agonist: a) produced marked tolerance and cross-tolerance to the rate-decreasing effects of CB₁ receptor agonists on schedule-controlled responding in monkeys; b) increased the potency with which CB₁ receptor antagonists disrupted schedule-controlled behavior; c) attenuated the behaviorally disruptive effects of methamphetamine and the DA D₂-family agonist R-(-)-NPA without substantively altering the behavioral effects of other dopaminergic ligands including the D₁-family agonist SKF82958 and the DA D₁- and D₂-family receptor blockers SCH23390 and haloperidol, respectively; and d) did not substantively alter the effects of the opioid µ agonist morphine or the nonselective opioid antagonist naltrexone. In distinction to previous findings of behavioral disruption upon cessation of chronically administered Δ⁹-THC in monkeys (Beardsley et al., 1986; McMahon, 2011), no signs of withdrawal-related physical discomfort or alteration in operant performance were evident upon discontinuation of the chronic regimen of AM411. Such differences may reflect, at least partly, a slower offset in action for AM411 than for Δ⁹-THC (Delatte and Bergman, unpublished results), perhaps reflecting a more gradual reduction in plasma and brain levels. This idea is consistent with previous findings showing that the severity of spontaneous withdrawal with other dependence-inducing drugs, e.g., morphine, may be lessened by gradual reductions in dosage (Bergman and Schuster, 1985).

CB₁ tolerance and cross-tolerance. Tolerance developed to the effects of chronic treatment with AM411 in a manner that is generally consistent with previous findings of tolerance to the effects of Δ⁹-THC on schedule-controlled behavior in monkeys. Notwithstanding the daily administration of initially high doses of AM411, response rates recovered to within
approximately 20% of pre-chronic control values within 4-8 days of treatment. Tolerance to the effects of a behaviorally comparable dosage of Δ⁹-THC in monkeys (1.0 mg/kg, administered twice daily) developed somewhat more slowly (i.e., 20–24 days; McMahon, 2011); however, based on ED₅₀ values for Δ⁹-THC in the two studies, the magnitude of changes in sensitivity is highly comparable suggesting similar changes in the sensitivity of underlying CB₁ receptor mechanisms.

The present findings also are consistent with previous reports of cross-tolerance between Δ⁹-THC and other CB₁ receptor agonists (Panagis et al., 2008; Singh et al., 2011; McMahon, 2011) and extend them to include cross-tolerance to the rate decreasing effects of the CB₁ receptor agonists methanandamide, Δ⁹-THC, AM4054, and WIN55,212.2 in AM411-treated subjects. The magnitude of cross-tolerance to WIN 55-212.2, Δ⁹-THC, and AM4054 were generally similar in the present studies, whereas chronic treatment with AM411 produced significantly greater tolerance to its own effects and those of methanandamide. Thus, even doses of AM411 and methanandamide ≥100 mg/kg failed to substantively decrease response rates during the chronic regimen, precluding accurate estimations of the tolerance that developed. The gradation in tolerance to CB₁-mediated behavioral effects (i.e., AM4054 ≈ WIN55,212.2 < Δ⁹-THC < methanandamide, AM411), is consistent with these drugs differing in intrinsic efficacy at the CB₁ receptor—even though such differences typically are not apparent in studies of their acute effects. For example, the CB₁ putative partial (Δ⁹-THC) and full (CP55,940 or WIN55,212.2) agonists produce comparable antinociceptive, motoric, or hypothermic effects when administered acutely (Chaperon and Thiebot, 1999) reflecting the low fractional occupancy that appears to be sufficient for such CB₁-mediated behavioral effects (Singh et al., 2011; McMahon, 2011). In the present studies, however, the fractional occupancy required for rate-
...decreasing effects presumably increased during chronic treatment with AM411, perhaps as a result of CB₁ receptor desensitization or down-regulation. Consequently, only ligands with sufficient efficacy, i.e., that did not require high levels of occupancy, still could decrease response rates (Sim et al., 1996; Breivogel et al., 1999).

The proposed role of efficacy in the present studies is consistent with previous findings using other biological endpoints (e.g., inhibition of adenylyl cyclase or smooth muscle contraction; Selley et al., 2004; Pertwee et al., 1993). From this perspective, the present results suggest that the CB₁ agonists AM411 and methanandamide, like Δ⁹-THC, are best characterized as CB₁ partial agonists. In this regard, methanandamide previously has been shown to only partially mimic Δ⁹-THC-like discriminative stimulus effects in rats (Jarbe et al., 1998), which may be a further indication of its partial agonist activity (Lamb et al., 2000). Yet, this suggestion must be viewed cautiously in light of the limited number of studies that address the in vivo efficacy of these ligands.

Enhanced sensitivity to CB₁ antagonists. The increased potency with which both the CB₁ inverse agonist, rimonabant, and the CB₁ neutral antagonist, AM4113, decreased response rates during chronic AM411 treatment extend previous observations in Δ⁹-THC-treated subjects (Lamb et al., 2000; McMahon, 2011) and are analogous to the increased behavioral sensitivity to antagonists or inverse agonists observed during chronic treatment with other classes of drugs, e.g., opioids or benzodiazepines (Goldberg and Schuster, 1967; McMahon and France, 2002). Based upon evidence from these pharmacological classes, such increased sensitivity in the present studies may reflect increases in negative efficacy (Liu and Prather 2001, 2002; McMahon and France, 2002). However, this idea remains speculative in the absence of further direct evidence.
Previous studies also have delineated pharmacological distinctions between the CB₁ inverse agonist rimonabant and novel cannabinoid CB₁ receptor neutral antagonists (e.g., AM4113) in signal transduction and in their physiological or behavioral actions (McLaughlin et al., 2006; Sink et al., 2008; Bergman et al., 2008). The leftward shift in dose-response function was noticeably greater for rimonabant (>2 log units) than for AM4113 (<1.5 log unit) in the present studies. The extent to which simply displacement of AM411 from its binding site contributes to the observed effects of rimonabant and AM4113 in chronically treated subjects is unknown. It is also unclear whether the difference in increased sensitivity of rimonabant and AM4113 can be attributed to differences in mechanism ascribed to the two drugs, i.e., inverse agonism vs. neutral antagonism. Earlier studies with GABAₐ ligands have not supported the idea that the magnitude of increased sensitization varies in relation to efficacy of antagonists and inverse agonists (Martin et al., 1995; McMahon et al., 2002). Though some tendency to greater increases in potency for neutral as compared with inverse agonists, the effects of GABAₐ and CB₁ ligands are mediated differently (i.e., ion channel vs. GPCR signaling) and the extent to which conclusions can be applied across these types of systems is unknown.

**CB₁ drug dependence.** The association between CB₁ agonist-induced tolerance and classical physical dependence generally has been controversial. Signs of physical distress that might indicate an abstinence syndrome have not been easily identified after discontinuation of chronic CB₁ agonist treatment (spontaneous withdrawal) or administration of rimonabant (antagonist-precipitated withdrawal) (Panagis et al., 2008). Early studies in monkeys showed that the discontinuation of chronic i.v. infusion of Δ⁹-THC led to the disruption of schedule-controlled responding, which could be attenuated by the resumption of chronic treatment (Beardsley et al.,
1986). However, these effects occurred without clear physical distress, and may have reflected only the offset of the effects of Δ⁹-THC, leading the authors to conservatively describe their results as denoting ‘behavioral dependence’, which did not imply other changes in underlying substrate. More recently, studies of withdrawal from chronic CB₁ agonist treatment have reported signs of physical dependence, e.g. increased wakefulness in humans and monkeys upon spontaneous withdrawal, or increased frequency of paw tremors and head-shaking in mice and monkeys upon antagonist-precipitated withdrawal (Budney et al., 2004, Lichtman et al., 2001, Stewart and McMahon, 2010). The increased sensitivity to rimonabant and AM4113 in the present studies is consistent with changes in behavioral sensitivity to the effects of rimonabant observed in Δ⁹THC–treated rodents and monkeys and, accordingly, may reflect physical dependence (Singh et al., 2011; McMahon, 2011). However, this view should be considered carefully for several reasons. First, the utility of increased sensitivity to the effects of CB₁ antagonists during chronic treatment as a marker of physical dependence is not firmly established. Thus, increased sensitivity to the disruptive effects of rimonabant on operant behavior in previous studies of Δ⁹THC–treated rats was not maintained over the course of repeated determinations (Lamb et al., 2000). It is difficult to imagine that physical dependence, if present, subsided during chronic treatment in those studies. Second, as suggested above, antagonist-precipitated disruptions in operant behavior in the present studies may be attributable to the abrupt offset of agonist action (Beardsley et al., 1986). Finally, increases in head-shaking after rimonabant, reported in Δ⁹-THC–treated rhesus monkeys by Stewart and McMahon (2010), were not prominent after rimonabant or AM4113 treatment in the present experiments. Such effects on overt behavior may be species-or context-dependent; nonetheless, doses of rimonabant that disrupted operant behavior in AM411-treated squirrel monkeys did not reveal easily-
identifiable or consistent effects on overt behavior aside from profuse salivation. However, profuse salivation can be observed following the repeated administration of rimonabant itself and, thus, cannot be viewed as a sufficient indicator of physical dependence (unpublished observations; include rimonabant-induced scratching in non dependent rats/mice (e.g., Janoyan et al., 2002; Jarbe et al., 2006; Schlosburg et al., 2011). Taken together, the above findings suggests that the term ‘behavioral dependence’—which, beyond displacement of the agonist from its binding site, does not presume alterations in substrate that mediate physical dependence—still may be the most appropriate term to describe changes in operant behavior that are precipitated by an antagonist either during chronic CB₁ agonist treatment or following its discontinuation.

**Effects of μ-opioid and DA ligands.** Evidence from other studies suggests that complex neurochemical and behavioral interactions exist between CB₁–opioid–DA systems that may contribute importantly to the addiction liability of cannabinoids (Maldonado, 2002; Tanda and Goldberg, 2003). In the present study, chronic AM411 treatment failed to alter the effects of either morphine or naltrexone on response rates, indicating that tolerance to the effects of CB₁ agonists is mediated via brain mechanisms that do not prominently involve μ-opioid systems. With regard to CB₁–DA interactions, previous studies in non-human primates have demonstrated that co-administration of a threshold dose of levonantradol and a DA D₂-like receptor agonist (quinelorane) precipitated marked sedation, ptosis, and decreased general activity and locomotor behavior. In contrast, co-administration of levonantradol and the DA D₁-like receptor agonist SKF81297 had no effect, highlighting the specificity of the interaction between CB₁ and DA D₂-like systems (Meschler et al., 2000). In the present studies, the effects of acute AM411 treatment
in combination with a D2-like agonist were not studied, precluding the collection of additional evidence for such DA receptor subtype-selective interactions with a CB1 agonist. However, consistent with such selective interactions, chronic AM411 treatment produced cross-tolerance to the effects of the direct DA D2-like receptor agonist, R-(-)-NPA and no change in the effects of the direct DA D1-like agonist SKF82958. Cross-tolerance to the rate-decreasing effects of the indirect DA agonist methamphetamine also was observed, implicating the involvement of DA D2-like receptor mechanisms. However, the lack of significant changes in the effects of the DA D2-like antagonist, haloperidol indicates that such CB1 and DA D2-like interactions may not occur at the receptor level but, rather, involve common downstream actions.
ACKNOWLEDGEMENTS

We thank Lindsey Wood and Wyatt Traina for expert technical support, and Carol A. Paronis for comments on an earlier version of this manuscript.
AUTHORSHIP CONTRIBUTION

Participated in research design: Desai, Bergman

Conducted experiments: Desai

Contributed new reagents: Makriyannis, Thakur, Vemuri, Bajaj

Performed data analysis: Desai, Bergman

Wrote or contributed to the writing of the manuscript: Desai, Bergman

LEGENDS FOR FIGURES

**Figure 1:** Effects of the cannabinoid CB₁ agonist, AM411 in squirrel monkeys responding under a FR30 schedule of stimulus-shock termination before and during chronic treatment with i.m. 1.0 mg/kg/day AM411. Abscissa: pre-chronic vehicle, 0.32, and 1.0 mg/kg AM411, and days of chronic treatment with AM411 (0.32 mg/kg: open squares; 1.0 mg/kg: open triangles); Ordinates: rate of responding as a percentage of control rates. Points are means (+ S.E.M.) based on data from three or four monkeys. Open circle above pre-chronic “V” represents mean control values (100% ± average S.D.) over the five sequential components of the session. Dotted line represents mean 100% averaged across session components. Capped solid lines indicate treatment dose of AM411 in mg/kg/day. Note: between days 40 – 460, if data for 1.0 mg/kg AM411 were not available for a subject on a particular day, e.g., due to test sessions with other doses of drugs or weekends, data for that subject from the next 1.0 mg/kg AM411 control session were used to calculate the plotted group response rate. * indicates significantly different from vehicle control value.

**Figure 2:** Effects of the cannabinoid CB₁ agonist, AM411 in squirrel monkeys responding under a FR30 schedule of stimulus-shock termination before (open circles) and during (closed circles) chronic treatment with i.m. 1.0 mg/kg/day AM411. Abscissa, single AM411 dose, log scale; ordinate (left and right panel): rate of responding as a percentage of control rates. Points are means (+ S.E.M.) based on data from three or four monkeys. Open and closed circles above pre-chronic “V” and chronic “V”, respectively, represent mean control values (100% ± average S.D.) under the FR30 stimulus-shock termination schedule in the five sequential components of the session. Control data for pre-chronic AM411 are re-plotted from figure 1. Dotted line represents mean 100% averaged across session components.

**Figure 3:** Effects of the cannabinoid CB₁ receptor agonists AM4054, WIN55,212.2, Δ⁹-THC, and methanandamide in squirrel monkeys responding under the FR30 schedule of stimulus-shock termination. Other details as in figure 2.

**Figure 4:** Effects of the cannabinoid CB₁ receptor antagonists, SR141716A and AM4113, administered i.v. via the tail vein in squirrel monkeys responding under the FR30 schedule of stimulus-shock termination. Other details as in figure 2.

**Figure 5:** Effects of the indirect DA agonist, methamphetamine and the DA D₂ receptor agonist, R-(−)-NPA, in squirrel monkeys responding under the FR30 schedule of stimulus-shock termination. Abscissa: cumulative dose, log scale. Other details as in figure 2.
Table 1: Effective doses, their 95% confidence intervals, and relative potencies with which cannabinoid CB₁ receptor agonists, cannabinoid CB₁ receptor antagonist, dopaminergic and opioid drugs decreased schedule-controlled behavior in squirrel monkeys before and during repeated exposure to the cannabinoid CB₁ receptor agonist, AM411 (1.0 mg/kg/day). Text in italics represents significant difference in relative potency values between pre-chronic vs chronic effects of drugs.
