Aberrant Histone Acetylation Promotes Mitochondrial Respiratory Suppression

In the Brain of Alcoholic Rats

Abstract

The acetylation of histone proteins in the core of DNA regulates gene expression, including those affecting mitochondria. Both histone acetylation and mitochondrial deficit have been implicated in neuronal damage associated with drinking problems. Many alcoholics repeat unsuccessful attempts at abstaining, developing a pattern of repeated drinking and withdrawal. Here, we investigated whether aberrant histone acetylation contributes to mitochondrial and cellular damage induced by repeated ethanol withdrawal (EW). We also investigated whether this effect of histone acetylation involves a small non-coding RNA (microRNA) let-7f. Male rats receive two cycles of an ethanol/control diet (7.5%, four weeks) and withdrawal. Prefrontal cortex was collected to measure mitochondrial respiration and histone acetylation using XF real-time respirometry and gold immunostaining, respectively. Separately, HT22 (mouse hippocampal) cells received two cycles of ethanol exposure (100 mM, 20 hours) and withdrawal. Histone acetylation promoter (Trichostatin A, TSA) and let-7f antagonir were applied during withdrawal. Mitochondrial respiration, let-7f level, and cell viability were assessed using XF respirometry, qPCR, TaqMan let-7f primers, and Calcein-AM assay, respectively. Repeated ethanol withdrawn rats show more than a twofold increase in histone acetylation, accompanied by mitochondrial respiratory suppression. EW-induced mitochondrial respiratory suppression is exacerbated by TSA treatment in a manner that is attenuated by let-7f antagonir cotreatment. TSA treatment does not alter the increasing effect of EW on let-7f level but dramatically exacerbates cell death induced by EW. These data suggest that the multiple episodes of withdrawal from chronic ethanol impede mitochondrial and cellular integrity through upregulating histone acetylation, independently or additively with let-7f.
Introduction

Long-term heavy drinking often results in alcoholism of which symptoms include craving for drinking, loss of self-control, organ damage, and withdrawal syndromes. Withdrawal syndromes such as anxiety and seizure can occur upon the abrupt termination of long-term heavy drinking. Many alcoholics repeat drinking and withdrawal, risking brain damage and premature death (George et al., 1990; Becker and Hale 1993; NIAAA, 1995; Krystal et al., 1997; Stephens et al., 2001). The premature death occurs even after complete abstinence (Marmot et al., 1981; Holahan et al., 2010). However, the exact mechanism underlying this problem and a preventative strategy remain obscure.

Mitochondria are the major source of cellular energy, critically affecting cell death and survival decision. Damaged mitochondria are unable to provide ATP necessary for ATP-synthesizing enzyme and glutamate metabolism, provoking excitotoxic stress (Jamme et al., 1995; Eisenberg et al., 2000; Fighera et al., 2006). Mitochondria from ethanol withdrawn rats show oxidized mitochondrial proteins (Jung et al., 2008) and electron transfer deficit. In inner mitochondrial membranes, electrons are transferred across the four enzyme complexes (I-IV) for mitochondrial respiration and ATP synthesis. Of importance, cytochrome c oxidase (CcO) is the terminal enzyme complex (IV) that consumes most of mitochondrial O2 to help produce ATP. Due to its critical role in ATP production, damage to CcO inevitably impedes mitochondrial function, provoking aberrant neurotransmission accompanied by ATP loss (Sanchez-Prieto et al., 1988). Our previous study has demonstrated that EW damages CcO, in turn suppressing mitochondrial respiration (Jung et al., 2011, 2012).
Histones are a protein family located in the core of the DNA wrap and pack DNA inside the small nucleus. Recent studies have discovered that the modification of histones such as histone acetylation plays an important role in gene expression including genes that regulate mitochondrial function (Wagner and Payne, 2011). Histone acetylation is regulated by a balance between histone acetyltransferase and histone deacetylase (Kwon et al., 2002). Histone acetyltransferases transfer acetyl moiety to lysine residues within histones, which enables transcriptional regulatory proteins to assess chromatin for gene activation (Kuo and Allis, 1998; Struhl, 1998; Peterson and Laniel, 2004). Histone deacetylases catalyze the removal of acetyl groups in the histone (Kuo and Allis, 1998), inhibiting gene expression. Ethanol has been reported to increase histone acetylation. Treatment of hepatocytes with ethanol for 24 hours increased histone acetylation (Park et al., 2003). Ethanol is metabolized to acetaldehyde and subsequently to acetate. Acetate is converted to acetyl-coenzyme A (Ugarte and Iturriage, 1976) which is required by histone acetyltransferase to acetylate histone (Breen et al., 1971; Smith et al., 1986). On the other hand, an increase or a decrease in histone acetylation has been reported in the brain of ethanol withdrawn rats (Pandey et al., 2008; Pascual et al., 2012). These studies show that aberrant histone acetylation may mediate ethanol consumption or ethanol withdrawal (EW)-related CNS disorders, making them important drug targets to manage alcoholism.

MicroRNAs are a class of small, 18-23 nucleotide, non-coding RNAs that largely downregulate gene expression through base pairing the 3′ untranslated region of messenger RNA (mRNA) (Djuranovic et al., 2012). A single microRNA can target hundreds of mRNA, affecting a variety of biological as well as pathological processes including those associated with ethanol (Sathyan et al., 2007; Pietrzykowski et al., 2008; Tang et al., 2008; Miranda et al., 2010). A particular
microRNA, let-7f, belongs to the let-7 family and has been associated with ethanol and mitochondria. Increased let-7f level occurs in the brain of the postmortem human alcoholics (Lewohl et al., 2011) and in alcoholic rats (Jung and Metzger, 2014). let-7f is highly expressed in human mitochondria (Sripada et al., 2012) and in cells whose death depends on mitochondria compared to mitochondria-independent cells (Shell et al., 2007).

As such, both histone acetylation and let-7f are implicated in the effect of ethanol/withdrawal and mitochondria. However, it is unknown whether histone acetylation adversely influences mitochondria challenged by repeated-EW, and whether let-7f is involved in this process. To this end, we investigated whether histone acetylation plays a role in mitochondrial damage through let-7f under the condition of repeated-EW. We used the model of repeated drinking/ethanol exposure and withdrawal because it mimics the drinking pattern of many alcoholics who repeat unsuccessful attempts at abstaining (George et al., 1990; Becker and Hale 1993; NIAAA, 1995; Krystal et al., 1997; Stephens et al., 2001). We report that repeated-EW increases histone acetylation in a manner that suppresses mitochondrial respiration and cell survival. This effect of histone acetylation appears to occur independently or additively with let-7f.

**Materials and methods**

**Materials**

Major analytic reagents were purchased from Qiagen Inc. (Valencia, CA), Sigma Aldrich (St. Louis, MO), Santa Cruz Biotechnology (Santa Cruz, CA), Mitosciences (Eugene, OR), and Seahorse Bioscience (North Billerica, MA). Reagents for histone acetylation assay were from Zymo Research (Orange, CA), Roche Diagnostic Corporation (Indianapolis, IN), and Bio-Rad.
Laboratories (Hercules, CA). Diet ingredients were obtained from Research Organics (Cleveland, OH) or MP Biomedicals (Irvine, CA). HT22 cells, a murine hippocampal cell line, were the generous gift of Dr. David Schubert (Salk Institute, San Diego, CA).

Animal experimental protocols

Male Sprague-Dawley rats, aged 3 months, were housed individually at 22-25°C and 55% humidity, with ad libitum access to water and a 12-hour light/dark cycle. All animal experimentation was conducted in accordance with the Guide to the Care and Use of Laboratory Animals [DHHS/NIH 85-23, 1996, Office of Science and Health Reports, DRR/NIH] and was approved by the University of North Texas Health Science Center Animal Care and Use Committee.

Ethanol program

Rats (7 rats/group) were assigned to two groups, such that one group received an ethanol program consisting of two cycles of a liquid diet containing 7.5% (v/v) ethanol for four weeks followed by withdrawal for two weeks. Another group (control diet group) was fed a liquid diet with dextrin isocalorically substituted for ethanol. The concentration of ethanol was gradually increased to 7.5% during the first week of the ethanol program, as described in our previous study (Jung et al., 2011). The physical appearance and body weights were monitored daily. We did not include a chow pellet group to compare the effect of a dextrin and a chow pellet diet on study end points. We have repeatedly observed that there is no significant difference between a dextrin diet vs a regular chow diet in vital signs including physical appearance and body weights (supplemental Figure A). Animals were fed chow pellets during withdrawal periods.
For an in vitro ethanol program, HT22 cells (mouse hippocampal cell line) were used, as they have shown a consistent effect of EW on mitochondria and cell viability in our previous studies (Jung et al., 2011). HT22 cells were cultured in flasks until they reached 70% confluence, according to a method established by Perez et al. (2005). The cells were then subjected to the ethanol program consisting of two cycles of ethanol exposure (0 or 100 mM, 20 hour) and withdrawal (four hours). 2-deoxyglucose (2-DG, glycolysis inhibitor), Trichostatin A (TSA, histone deacetylase inhibitor, histone acetylation promoter) or let-7f antagomir (inhibitor) were applied to HT22 cells during the first and the second EW phase or during the corresponding time period of control cells.

Brain tissue extraction
Rats were humanely sacrificed using the combination of xylazine (20 mg/kg, ip) and ketamine (100 mg/kg, ip) and the whole brain was harvested at the end of the ethanol program. Prefrontal cortex from each rat was used to measure mitochondrial respiration. A separate set of rats that received the same ethanol program was anesthetized and perfused intracardially with saline followed by 4% paraformaldehyde in phosphate-buffered solution (PBS). These fixed brain samples were used for gold immunolabeling to measure histone acetylation.

Gold immunolabeling of acetylated histones proteins
Rats were deeply anesthetized with pentobarbital (50 mg/kg) and then perfused intracardially with saline, followed by 4% ice-cold paraformaldehyde fixative. After fixation, the brain sample was soaked in 10% sucrose, followed by 20% and then 30% sucrose (prepared in 0.1 M PBS, pH7.4). The brain sample was then frozen, sectioned (20 µm) using a cryostat, and treated with
the antibody for acetylated histones H3 (Lys 9) (Millipore, Billerica, MA) for gold
immunolabeling, as described previously (Pandey et al., 2006). Histones are a protein family,
consisting of histone 1 through 5. We chose histone 3 (H3) because it is implicated in both
ethanol (Pandey et al., 2008) and mitochondria (McBrian et al., 2013). The quantification of
gold-immunolabeled proteins was performed using the Image Analysis System (Loats
Associates, Westminster, MD) connected to a light microscope that calculated the number of
immunogold particles/µm² in the prefrontal cortex at high magnification (100 x). The threshold of
each image was set up in such a way that an area without staining gave zero counts. Under this
condition, immunogold particles in the defined areas of five adjacent brain sections of each rat
were counted and values were averaged for each rat and group.

Mitochondrial respiration (mitochondrial O₂ consumption rate)
Mitochondrial O₂ consumption rate was measured according to the manufacturer’s instruction
(Seahorse Bioscience). For brain mitochondrial respiration, prefrontal cortex was obtained from
rats at the end of the ethanol diet program. Immediately thereafter, mitochondria were isolated
by conventional differential centrifugation as described in our previous study (Jung et al., 2011).
Mitochondria were then diluted with XF assay solution (KCL, KH2PO4, MgCL2, HEPES,
EGTA, and BSA), and transferred into XF24 cell culture plate. The plate was centrifuged (4°C,
at 3000 × g), added with succinate (substrate), incubated (37°C), and loaded into the XF24
respirometer. For cell mitochondrial respiration, HT22 cells (800 cells/well) were seeded into
each well of XF24 cell plate, cultured, and subjected to the aforementioned ethanol program.
The cell plate was then placed on an O₂ sensor cartridge and inserted to the XF respirometer.
TSA (0 or 400 nM) and/or let-7f antagomir (0 or 50 nM) was applied to HT22 cells during EW
phases. For both brain and HT22 cell samples, compounds that affect mitochondrial respiration were used to characterize the effect of repeated-EW on mitochondrial respiration. Those compounds were ADP (1 mM), oligomycin (2 µM, ATP synthesis inhibitor), let-7f antagonir (50 nM, acute treatment), NaN3 (CcO inhibitor, 1 mM), or FCCP (carbonilcyanide p-triflouromethoxy phenylhydrazone) (uncoupler, 0.6 µM). They were added to XF24 cell plate in a sequential order immediately after the XF24 respirometer read a basal O2 consumption rate. Data were normalized based on mitochondrial contents or cell numbers in each well.

let-7f quantification

The level of let-7f was measured in prefrontal cortex and in HT22 cells at the end of the ethanol program. Total RNA was isolated from brain tissues or cells using RNeasy kit (QIAGEN, Valencia, CA) and quantified using Agilent 2100 bioanalyzer (Agilent Technologies Inc. Santa Clara, CA). RNA was then reverse-transcribed to cDNA using TaqMan let-7f primers (for forward, 5’-GAAAGAGATTGATGTTT ATTTTAGAAG-3’; for reverse, 5’-AATTCACCTAAATTTA TAA TATCCTCT-3’) and the miScript reverse transcription kit (Qiagen, Valencia, CA). qPCR reactions were performed as follows: 50°C for 2 minutes, 95°C for 10 minutes, followed by 40 cycles of 95°C for 15 seconds and 60°C for 1 minute. Cycle threshold (Ct) values were calculated with SDS software v.2.3 (Applied Biosystems) using automatic baseline settings and a threshold of 0.2. The comparative Ct method was used to calculate the relative microRNA expression. The Ct value of an internal control gene (U6) was measured and subtracted from the corresponding Ct value for let-7f gene to calculate the ΔCt value.
Calcein-acetoxymethyl (Calcein-AM) ester viability assay

Cell viability was quantified using the membrane-permeant Calcein-AM ester dye (Invitrogen, Carlsbad, CA). HT22 cells received the aforementioned ethanol program. The cells were then treated with Calcein-AM for 30 minutes. TSA (0 or 400 nM) with or without a CcO inhibitor (NaN₃, 5 µM) or let-7f antagonist (0 or 50 nM) was applied to cells during EW phases. After the removal of the medium from the 96-well plates, the cells were rinsed once with PBS, and incubated in a solution of 2.5 µM Calcein-AM in PBS. Twenty minutes later, fluorescence was determined using a BioTek FL600 microplate reader (BioTek Instruments, Winooski, VT) with an excitation/emission filter set at 495/515 nm. Cell culture wells treated with methanol served as blanks. The results, obtained in relative fluorescent units, were expressed as the percentage of non-ethanol, control media values.

Pearson correlation assay

The physiological relationship between mitochondrial respiration, histone acetylation, and let-7f was assessed using the prefrontal cortex obtained from rat study and Pearson correlation statistical assay. To do this, the level of let-7f was measured in the same rats that were used to measure histone acetylation, and mitochondrial respiration. The Pearson correlation coefficient (r), a degree of correlation between two independent variables, was computed between two variables: mitochondrial respiration vs. histone acetylation, mitochondrial respiration vs. let-7f, or histone acetylation vs. let-7f. Results were presented as the value of r and p (probability of significant correlation).
Statistical analysis

Student t-test was used to analyze the data of histone acetylation. One-way or two-way ANOVA was used to analyze the data of one factor (basal mitochondrial respiration, let-7f level, or cell viability) or two factors [mitochondrial respiration with drug treatment (ethanol treatment x drug treatment)]. ANOVA was followed by a post hoc Tukey’s test to identify a specific difference between groups. Values were expressed as mean ± standard error of mean (S.E.M). The p value < 0.05 was used to indicate statistical significance.

Results

Characterization of the mitochondrial respiration of ethanol withdrawn rat

We characterized the mitochondrial respiration of ethanol withdrawn rats using compounds that affect mitochondrial respiration (Figure 1). The basal mitochondrial respiration without any drug treatment is lower in ethanol withdrawn rats than control diet rats (p = 0.002). For control rats, the addition of ADP to mitochondria stimulates mitochondrial respiration as ADP is converted to ATP as a coupling reaction between mitochondrial respiration and ATP synthesis (p = 0.05 vs. basal mitochondrial respiration). The addition of ATP synthase inhibitor oligomycin to mitochondria of control diet rats decreases mitochondrial respiration (p = 0.001 vs. mitochondrial respiration stimulated by ADP treatment). FCCP uncouples mitochondrial respiration from ATP generation by dissipating the electrochemical gradient (membrane potential). FCCP treatment to mitochondria normally maximizes mitochondrial respiration to maintain electrochemical gradient across mitochondrial membranes as seen in the mitochondria of control diet rats (p <0.0001 vs. mitochondrial respiration suppressed by oligomycin treatment). By contrast, mitochondria from ethanol withdrawn rats show a blunt response to the
addition of ADP, oligomycin, or FCCP. The addition of CcO inhibitor (NaN₃) inhibits the mitochondrial respiration of both control and ethanol withdrawn rats (p < 0.002 vs. mitochondrial respiration after FCCP treatment). These data suggest that the coupling function is not efficient in ethanol withdrawn rats. They also indicate that EW impedes the maximal respiratory capacity of mitochondria in response to ATP demand.

Effects of 2-deoxyglucose (2-DG, glycolysis inhibitor) on mitochondrial respiration

For most mammalian cells, the majority of cellular energy (38 ATP) is supplied from mitochondrial oxidative phosphorylation and minimal ATP is supplied from glucose break-down (glycolysis) (2 ATP) that takes place in cytoplasm. This difference in ATP production between mitochondrial oxidative phosphorylation and glycolysis is dramatically reduced in a disease condition such as cancer (Nakashima et al., 1984). 2-DG is phosphorylated by hexokinase, an enzyme that catalyzes the first step of glycolysis. This phosphorylated molecule (2-DG-6P) cannot be metabolized, thereby blocking the further process of glycolysis. Using 2-DG, we compared the extent of glycolysis-driven mitochondrial respiration between control and ethanol withdrawn HT22 cells. While 2-DG treatment does not significantly alter the mitochondrial respiration of control cells, it exacerbates (†p < 0.001) the already suppressed (*p < 0.002) mitochondrial respiration of ethanol withdrawn cells (Figure 2). This indicates that mitochondria from ethanol withdrawn cells heavily rely on glycolysis.

Effects of repeated-EW on histone acetylation

Previous investigations have shown a decrease or an increase in histone acetylation under the condition of EW. When measured two weeks after last ethanol feeding, we found more than a
twofold increase (p < 0.0001) in histone acetylation in the prefrontal cortex of ethanol withdrawn rats compared to control diet rats (Figure 3). These results indicate that repeated-EW from chronic ethanol feeding provokes the upregulation of histone acetylation in this brain area.

Effects of histone acetylation on mitochondrial respiration

Numerous studies have used histone deacetylase inhibitor TSA to determine the involvement of histone acetylation in brain disorders associated with ethanol (Pascual et al., 2012; You, et al., 2013). Using TSA, we determined whether histone acetylation is an upstream mediator that triggers EW-induced mitochondrial respiratory damage. We measured the mitochondrial respiration of ethanol withdrawn cells in the presence or absence of TSA and/or let-7f antagonir. Repeated-EW suppresses mitochondrial respiration (*p < 0.01) in a manner that is further suppressed by TSA treatment (**p < 0.002), most notably during the basal mitochondrial respiration (Figure 4A). This effect of TSA is attenuated by let-7f antagonir (†p < 0.05) that was applied to both phases of EW (total 8 hours). However, when let-7f antagonir was acutely applied (marked with an arrow in Figure 4A), it failed to improve mitochondrial respiration. CcO inhibitor (NaN₃) treatment suppresses the mitochondrial respiration of both ethanol withdrawn and control cells (p < 0.01). FCCP that was applied to cells subsequent to CcO inhibitor treatment failed to maximize mitochondrial respiration. This suggests that mitochondria are unable to reach maximal respiration if CcO damage is preceded. These data indicate that EW-induced histone acetylation impedes basal mitochondrial respiration and maximal respiratory capacity. For the effect of TSA on the basal respiration of control cells (Figure 4B), TSA treatment also decreased (***p < 0.001) mitochondrial respiration in a manner that is attenuated by let-7f antagonir cotreatment (†p = 0.02).
Effects of histone acetylation on the level of let-7f

We determined whether EW-induced histone acetylation increases the level of let-7f. As we previously reported (Jung et al., 2014), repeated-EW increases the level of let-7f (*p < 0.001) (Figure 5). However, TSA treatment during EW does not alter the level of let-7f in ethanol withdrawn cells or control cells (data not shown). Given this, the aforementioned decreasing effect of TSA on mitochondrial respiration is unlikely through the effect of histone acetylation on let-7f.

Effects of histone acetylation on cell viability

The cellular consequence of EW-induced histone acetylation was tested by assessing cell viability using Calcein-AM assay. The viability of control cells was not altered by TSA treatment but decreased by the combination of TSA with CcO inhibitor NaN3 treatment (*p < 0.01). EW suppresses cell viability and this effect is strikingly exacerbated by TSA treatment (†p < 0.001) (Figure 6). The cotreatment of TSA and NaN3 virtually left no live (spindle shape) ethanol withdrawn cells. When let-7f antagonir was applied to ethanol free control cells or ethanol withdrawn cells, it tended to increase the cell viability of control cells or significantly (‡p < 0.01) increased that of ethanol withdrawn cells. These data indicate that CcO inhibition creates a milieu favorable for the adverse effect of TSA on cell survival. Notice that the viability of control cells treated with the combination of TSA with CcO inhibitor resembles that of vehicle-treated ethanol withdrawn cells. Collectively, this raises a possibility that cell death induced by EW is attributed to the combined effect of histone acetylation upregulation, CcO damage, and excessive let-7f level.
Physiological relationship between mitochondrial respiration, histone acetylation, and let-7f

Pearson correlation assay indicates that there is a significant inverse relationship between the level of mitochondrial respiration vs. histone acetylation ($r = -0.49$, $p < 0.0001$) or let-7f ($r = -0.40$, $p = 0.007$) such that rats with a higher level of histone acetylation or let-7f show a lower level of mitochondrial respiration (Figure 7). However, no significant correlation was found between the level of histone acetylation or let-7f among these rats. These data suggests that EW-induced upregulation of histone acetylation contributes to mitochondrial respiratory suppression, independently or indirectly from the effect of let-7f.

**Discussion**

It is a common phenomenon that human alcoholics undergo multiple cycles of heavy drinking and withdrawal, and this increases the risk of brain damage (Ballenger and Post, 1978; Brown et al., 1988). Using the model of repeated ethanol consumption and withdrawal, the current study has demonstrated that repeated-EW from lengthy and heavy ethanol consumption increases histone acetylation in the brain of rats, accompanied by mitochondrial respiratory deficit. The mitochondrial deficit is exacerbated by TSA treatment but attenuated by the cotreatment with let-7f antagonim. These findings suggest that the multiple episodes of chronic ethanol consumption and withdrawal damages mitochondrial integrity through mechanisms involving the upregulation of histone acetylation and let-7f.

We first characterized the effect of repeated-EW on mitochondrial respiration using compounds that affect mitochondria. Due to the coupling reaction with ATP generation, mitochondrial respiration is normally increased by ADP or uncoupler FCCP, and decreased by oligomycin.
However, none of ADP, oligomycin, and FCCP treatments was able to alter mitochondrial respiration under repeated-EW condition, indicating an inefficient coupling function. The failure of ADP to stimulate mitochondrial respiration may also indicate that EW depletes ATP, and thus, mitochondrial respiration becomes ATP independent. Instead, mitochondrial respiration during EW may be influenced by a second messenger molecule, cyclic adenosine monophosphate (cAMP). This view is based on a report that an aberrant signaling mechanism associated with cAMP mediates EW-induced anxiety (Pandey et al., 2003). A CcO inhibitor decreased mitochondrial respiration in both control and ethanol withdrawn rats, indicating the essential role of CcO in mitochondrial respiration. When mitochondrial ATP generation is malfunctioning, a less efficient way of ATP generation (glycolysis) is increased. Glycolysis inhibitor 2-DG significantly inhibited the mitochondrial respiration of ethanol withdrawn cells, suggesting that ethanol withdrawn cells heavily rely on glycolysis for ATP generation. These data demonstrate that mitochondria from ethanol withdrawn rats undergo a respiratory and energetic crisis.

The acetylation of lysine residues of histone proteins regulates gene expression including genes affecting mitochondria (Wagner and Payne, 2011). The oncogene c-Myc contributes to histone acetylation by increasing the mitochondrial synthesis of acetyl-coenzyme A that provides an acetyl moiety for histone acetylation (Morrish et al., 2010). The increased histone acetylation may activate genes of mitochondrial apoptotic molecules (Zhang et al., 2004), promoting apoptotic damage to mitochondria. Studies using histone deacetylase inhibitors (promotes histone acetylation) support this idea such that apicidin induces cytochrome c leakage, activating apoptotic caspases in human leukemia cells (Kwon et al., 2002). Suberic bishydroxamate
induces the entry of apoptotic Bax to mitochondria (Zhang et al., 2004), triggering mitochondrial damage. We have demonstrated that repeated-EW provokes the leakage of mitochondrial cytochrome c in male rats (Ju et al., 2012) and the collapse of mitochondrial membrane potential in HT22 cells (Jung et al., 2009). These studies suggest that aberrant histone acetylation has a potential to impede mitochondrial integrity (Bernhard et al., 1999; Burgess et al., 2001) through factors involving mitochondrial apoptosis. Previous investigations of the effect of EW on histone acetylation have yielded controversial results. A decrease in histone acetylation occurs in the amygdaloid of ethanol withdrawn rats (Pandey et al., 2008). TSA treatment attenuates EW-induced anxiety in rats (You et al., 2013), suggesting a protective effect of histone acetylation. More relevant to our current study, Pascual et al. (2012) have observed that repeated ethanol feeding and withdrawal increased histone acetylation in the prefrontal cortex of adolescent rats but not in adult rats. By comparison, we observed more than a twofold increase in histone acetylation in ethanol withdrawn adult rats (Figure 1). Both our and Pascual’s studies used a program of repeated ethanol feeding and withdrawal but our ethanol program was much longer (total 12 weeks) than theirs (two weeks). This suggests that repeated-EW from a lengthy ethanol consumption may be more prone to increase histone acetylation than that from a short term ethanol exposure. It is also possible that histone acetylation was initially decreased during the acute phase of EW and later increased as a rebound response in our study. Alternatively, ethanol-induced increase in histone acetylation (Park et al., 2003) might have persisted throughout the late phase of EW. Taken together, one can argue that the effects of repeated-EW on histone acetylation depend on multiple factors including brain region, the length of ethanol feeding, and an early vs. late phase of EW.
We have recently demonstrated that EW-induced mitochondrial respiratory deficit is attenuated by let-7f antagomir treatment, suggesting that let-7f upregulation contributes to the mitochondrial deficit (Jung and Metzger, 2014). Increased let-7f has been shown in the postmortem brain of human alcoholics (Lewohl et al., 2011) and in alcoholic rats (Jung and Metzger, 2014). In particular, let-7f localizes in human mitochondria (Sripada et al., 2012) and inhibits CcO protein expression (Jung and Metzger, 2014). We thus tested whether let-7f mediates TSA’s inhibition of mitochondrial respiration. While let-7f antagomir treatment during a few hours of EW attenuated the inhibiting effect of TSA on mitochondrial respiration, acutely applied let-7f antagomir failed to do so. This might reflect a slow genomic process. If TSA and let-7f act at the genomic level, it may be a slow process where a change in gene expression takes effect at the level of mitochondria.

We subsequently determined whether histone acetylation induced by TSA treatment increases let-7f level in HT22 cells. TSA treatment did not alter the level of let-7f either in control or ethanol withdrawn cells (Figure 5), suggesting no direct interaction between histone acetylation and let-7f. Presumably, histone acetylation and let-7f suppress mitochondrial respiration through pathways independent of each other. In support of this view, no correlation was found between the level of histone acetylation and let-7f (Figure 7) in rat brain. By comparison, a strong inverse correlation was observed between the levels of mitochondrial respiration vs. histone acetylation or let-7f. These in vivo correlation data are consistent with data of cell mitochondrial respiration that was decreased and increased by TSA and let-7f antagomir treatment, respectively. This suggests that our cell model reflects a physiological aspect at the level of mitochondrial respiration, histone acetylation, or let-7f.
Although histone acetylation largely activates gene expression, it also inhibits the expression such that histone deacetylase inhibitor phenylbutyrate represses CcO gene in flies (Kang et al., 2002). This raises a possibility that histone acetylation inhibits CcO gene, thereby inhibiting mitochondrial respiration independently or additively with the inhibiting effect of let-7f on mitochondrial respiration. Notice that mitochondrial respiration after FCCP treatment is even lower than the basal level when FCCP is added to mitochondria subsequent to NaN3 (CcO inhibitor) (Figure 4A). When CcO is not functioning, mitochondria may lose its ability to maximize respiration in response to FCCP. Given these results, complex serial and parallel mechanisms may simultaneously affect mitochondria through factors associated with histone acetylation, let-7f, and CcO upon repeated-EW.

We finally determined a cellular consequence of an increase in histone acetylation by assessing the effect of TSA on cell viability. Studies on the effect of TSA on cell viability have yielded mixed results. TSA treatment protects rat cerebellar neurons from glutamate excitotoxicity (Leng and Chuang, 2006), controversially suppresses cell survival, and increases the apoptosis of dopaminergic neuronal cells (Wang et al., 2009). Histone deacetylase inhibitor suberic bishydroxamate increases mitochondrial membrane permeability and releases mitochondrial apoptogenic proteins in melanoma cells (Saito et al., 1999; Zhang et al., 2004). Of interest, the viability of control cells is not altered by TSA treatment but decreased by the combination of TSA and CcO inhibitor. Despite that histone acetylation induced by TSA suppresses mitochondrial respiration, control cells are resistant to the adverse effect of TSA on cell survival perhaps through intact endogenous defense mechanisms. However, when CcO is damaged, it may create a mitochondrial milieu favorable for TSA’s cytotoxicity, overriding the defense
mechanisms. In ethanol withdrawn cells, CcO deficit (Jung et al., 2011) and histone acetylation are already occurring even in the absence of CcO inhibitor or TSA treatment. Therefore, it is not surprising that the viability of vehicle-treated ethanol withdrawn cells resembles that of control cells cotreated with a CcO inhibitor and TSA. Further insult to ethanol withdrawn cells with TSA and/or CcO inhibitor virtually leaves few or no live cells.

In conclusion, our study provides empirical evidence that multiple withdrawals from lengthy and heavy drinking have a potential to activate histone acetylation and adverse downstream effects on mitochondrial and cellular homeostasis. Our findings may shed a new mechanistic insight involving histone acetylation and mitochondria into managing brain disorders associated with repeated unsuccessful attempts at abstaining.

Figure 1. Characterization of the mitochondrial respiration of ethanol withdrawn rats. Young adult male rats received an ethanol diet program consisting of two cycles of an ethanol/control diet for four weeks and withdrawal for two weeks. At the end of the ethanol program, rats were humanely sacrificed and prefrontal cortex was collected to measure mitochondrial respiration using XF respirometer. ADP (1 mM), oligomycin (ATP synthase inhibitor, 2 µM), FCCP (uncoupler, 0.6 µM), and NaN3 (CcO inhibitor, 5 µM) were added to mitochondria in a sequential order immediately after basal respiration was measured. For control rats, the addition of ADP increased mitochondrial respiration, which was subsequently decreased and then increased back by oligomycin and FCCP addition, respectively. Ethanol withdrawn rats show lower basal mitochondrial respiration ($p = 0.002$) and lack of response to ADP, oligomycin, or FCCP compared to control diet rats. CcO inhibitor (NaN3) inhibits the mitochondrial respiration of both control and ethanol withdrawn rats ($p < 0.002$). The time zero in X axis indicates the time when brain samples were loaded to the XF respirometer. Depicted are mean ± S.E.M. N = 6 or 7 rats/group. Some S.E.Ms are not shown due to their small values.

Figure 2. Effects of 2-deoxyglucose (2-DG, glycolysis inhibitor) on mitochondrial respiration. HT22 cells were plated in 24-well microplate and subjected to an ethanol program consisting of two cycles of ethanol exposure (0 or 100 mM) for 20 hours and withdrawal for four hours. 2-DG was added during the EW phases. At the end of the program, the microplate was placed on the O2 sensor cartridge and inserted into the XF respirometer. Basal O2 consumption rate was measured at four time points. Compared to control cells, ethanol withdrawn cells show lower mito-
chondrial respiration in a manner that is further lowered by 2-DG treatment. *p < 0.002 or **p
< 0.001 vs. control cells. †p < 0.005 vs. cells of repeated-EW. N =6 wells/each condition. De-
picted are mean ± S.E.M.

Figure 3. Effects of repeated-EW on histone acetylation.
Young adult male rats received an ethanol diet program consisting of two cycles of an etha-
nol/control diet for four weeks and withdrawal for two weeks. At the end of the ethanol pro-
gram, rats were deeply anesthetized and subjected to the process of brain perfusion and fixation.
Brains were sectioned and treated with the antibody against acetylated histones H3. Gold-
immunolabeled protein was quantified using the Image Analysis System connected to a light mi-
croscope that calculated the number of immunogold particles/µ² area of a defined prefrontal cor-
tex area at high magnification (100 x). Immunogold particles shown as dark deposits indicate
acetylated histones (H3) (Figure 3A). They are significantly more populated in ethanol with-
drawn rats than control diet rats (Figure 3B). *p < 0.0001 vs. control diet rats. Depicted are
mean ± S.E.M. N= 5 slides/rat for four rats in each group.

Figure 4. Effects of histone acetylation on mitochondrial respiration.
HT22 cells (800 cells/well) were plated in 24-well microplates and subjected to an ethanol pro-
gram consisting of two cycles of ethanol exposure (0 or 100 mM) for 20 hours and withdrawal
for four hours. TSA and/or let-7f antagomir were added during both phases of EW. The
microplate was then placed on the O₂ sensor cartridge and inserted into the XF respirometry.
Mitochondrial respiration was assessed by measuring O₂ consumption rate. Immediately after
basal O₂ consumption rate was read, oligomycin (2 µM), let-7f antagomir (50 nM), NaN3 (CₐO
inhibitor, 5 µM), and FCCP (0.6 µM) were added to cells in a sequential order. Compared with a control condition, repeated-EW suppresses basal mitochondrial respiration (*p < 0.01) and further so in the presence of TSA (**p < 0.002) (Figure 4A). This effect of TSA is attenuated after let-7f antagonomir cotreatment during the EW phases (†p < 0.05). However, acutely applied let-7f antagonomir (marked with arrow in this figure) fails to alter mitochondrial respiration. For the effect of TSA on control cells (Figure 4B), only basal respiration data are presented as a representative case. TSA decreased (**p < 0.001) the basal mitochondrial respiration of control cells in a manner that is attenuated by let-7f antagonomir cotreatment (†p = 0.02). Depicted are means for 16 wells/group and some S.E.Ms are omitted for figure clarity. *p < 0.001, **p < 0.0001 vs. control cells treated with vehicle at 100%.

Figure 5. Effects of histone acetylation on the level of let-7f.

HT22 cells were subjected to an ethanol program consisting of two cycles of ethanol exposure (0 or 100 mM) for 20 hours and withdrawal for four hours. TSA was applied during both EW phases. At the end of the program, total RNA was isolated and reverse-transcribed to cDNA using TaqMan let-7f primers and the miScript reverse transcription kit. qPCR reactions were performed to quantify the level of let-7f. An internal control gene (U6) was also measured and subtracted from the corresponding C_T value for let-7f gene to calculate the ΔC_T value. Compared to control cells without TSA treatment, ethanol withdrawn cells show an increase in the level of let-7f (*p < 0.001). This effect of EW is not altered by TSA treatment. Depicted are mean ± S.E.M for 6 wells/group. *p < 0.001 vs. control cells without TSA treatment at 1 with dash line.
Figure 6. Effects of histone acetylation on cell viability.

HT22 cells were subjected to an ethanol program consisting of two cycles of ethanol exposure (0 or 100 mM) for 20 hours and withdrawal for four hours. TSA (0 or 400 nM) with or without NaN3 (0 or 5 µM), and let-7f antagonir (50 nM) alone were applied during EW phases or the corresponding time period of control cells. At the end of the program, cell viability was assessed using Calcein-AM assay. Microscopic cell populations were assessed using a fluorescence microscope at the magnification of 100 x (Figure 6A). Fully confluent healthy cells with spindle-shaped morphology are shown in control cells. The viability of control cells is not altered by TSA treatment alone but decreased by the combination of TSA with CcO inhibitor NaN3 (*p < 0.01). Healthy cells with spindle shape morphology are much less populated, hardly shown, or do not exist in ethanol withdrawn cells treated with vehicle, TSA, or TSA + NaN3, respectfully. Except for control cells treated with TSA or let-7f antagonir, all treatment groups show a significantly lower cell viability (p < 0.01) than control cells treated vehicle at dash line (statistical symbols are omitted for this difference for figure clarity). *p < 0.01 vs. control cells treated with TSA, †p < 0.005 vs. ethanol withdrawn cells treated with vehicle or TSA+ NaN3. ‡p < 0.01 vs. ethanol withdrawn cells treated with let-7f antagonir. Depicted are mean ± S.E.M for 16 wells/group.

Figure 7. The relationship between changes in mitochondrial respiration, let-7f, and histone acetylation.

The levels of mitochondrial respiration, let-7f level, and histone acetylation were measured in the prefrontal cortex of rats using the method of XF respirometry, gold immunolabeling of acetylated histones proteins, and TaqMan let-7f primers, respectively. The data were analyzed using
Pearson correlation statistical assay to determine a physiological relationship between changes in the three variables. The degree of mitochondrial respiration was inversely correlated with that of let-7f (r = -0.4, p = 0.007) and histone acetylation (r = -0.49, p < 0.0001) whereas no correlation was found between the level of let-7f and histone acetylation. Depicted are multiple data points from 14 rats.

Figure legend: The effect of a dextrin diet and a chow pellet diet on body weights and mitochondrial stress.

Male rats (5 months old) were habituated for 7 days after arrival at a vivarium. They were divided into two groups (7 rats/group) based on a dextrin and a chow pellet diet. Body weights were measured every day for two weeks. Immediately thereafter, rats were sacrificed and prefrontal cortex was collected to assess mitochondrial stress by measuring mitochondrial membrane swelling (Jung et al., 2012). Intact mitochondria scatter light at 540 nm wavelength; mitochondrial swelling and rupture reduces mitochondrial light scattering and, thus, absorbance at 540 nm (a faster decline indicates more severe mitochondrial membrane swelling). Neither body weights nor mitochondrial membrane swelling showed a statistically significant difference between the two groups. N=7 rats/group.
