Recommended Section Assignment: Behavioral Pharmacology
ABSTRACT

Marijuana-dependent individuals report using marijuana to alleviate withdrawal, suggesting that pharmacotherapy of marijuana withdrawal could promote abstinence. To identify potential pharmacotherapies for marijuana withdrawal, this study first characterized rimonabant-induced Δ⁹-tetrahydrocannabinol (Δ⁹-THC) withdrawal in rhesus monkeys using drug discrimination and directly observable signs. Second, drugs were examined for their capacity to modify cannabinoid withdrawal. Monkeys receiving chronic Δ⁹-THC (1 mg/kg/12 h s.c.) discriminated the cannabinoid antagonist rimonabant (1 mg/kg i.v.) under a fixed ratio schedule of stimulus-shock termination. The discriminative stimulus effects of rimonabant were dose-dependent (ED₅₀ = 0.25 mg/kg) and were accompanied by head shaking. In the absence of chronic Δ⁹-THC treatment (i.e., in non-dependent monkeys), a larger dose (3.2 mg/kg) of rimonabant produced head shaking and tachycardia. Temporary discontinuation of Δ⁹-THC treatment resulted in increased responding on the rimonabant lever, head shaking, and activity during the dark cycle. The rimonabant discriminative stimulus was attenuated fully by Δ⁹-THC (at doses larger than 1/mg/kg/12 h) and the cannabinoid agonist CP 55940, and partially by the cannabinoid agonist WIN 55212-2 and the α₂-adrenergic agonist clonidine. In contrast, a benzodiazepine (diazepam) and monoamine agonist (cocaine) did not attenuate the rimonabant discriminative stimulus. Head shaking was attenuated by all test compounds. These results show that the discriminative stimulus effects of rimonabant in Δ⁹-THC treated monkeys are a more pharmacologically selective measure of cannabinoid withdrawal than rimonabant-induced head shaking. These results suggest that cannabinoid and non-cannabinoid (α₂-adrenergic) agonists are potentially useful therapeutics for marijuana dependence inasmuch as they attenuate the subjective experience of Δ⁹-THC withdrawal.
INTRODUCTION

Pharmacotherapy is a viable strategy for treating dependence to some drugs (e.g., opioid agonists and tobacco). Marijuana-dependent individuals are seeking treatment in increasing numbers and there is an emerging consensus that a pharmacotherapy could help promote abstinence from marijuana (Compton et al., 2004; Elkashef et al., 2008; Vandrey and Haney, 2009), although currently there are no FDA-approved pharmacotherapies for marijuana dependence. To facilitate identification of a suitable pharmacotherapy, pre-clinical assays of marijuana (i.e. cannabinoid) dependence are needed. Many people report using marijuana to alleviate withdrawal that emerges upon discontinuation of marijuana use; therefore, a pharmacotherapy could specifically target withdrawal to promote abstinence (Budney et al., 1999). The goals of this study were to use drug discrimination and directly observable signs to characterize cannabinoid withdrawal in rhesus monkeys and, further, to examine cannabinoids and non-cannabinoids for their capacity to modify cannabinoid withdrawal.

Dependence and withdrawal to $\Delta^9$-THC, the cannabinoid primarily responsible for the abuse and dependence liability of marijuana, has been examined in rodents, dogs, and monkeys. In rhesus monkeys, abrupt discontinuation of chronic $\Delta^9$-THC treatment resulted in a withdrawal syndrome, evidenced by increased gross movement, eye contact, and tooth-baring (Fredericks and Benowitz, 1980) and disruptions in operant responding for food (Beardsley et al., 1986). However, withdrawal was not always detected following discontinuation of chronic $\Delta^9$-THC treatment (Harris et al., 1974). Failure to detect withdrawal following discontinuation of chronic $\Delta^9$-THC could be due to the long duration of action and slow elimination of $\Delta^9$-THC (Grotenhermen, 2003). With the availability of the CB$_1$ antagonist rimonabant, previous studies were able to demonstrate that rimonabant induces a cannabinoid withdrawal syndrome in rodents.
and dogs (Lichtman and Martin, 2002 for review). The directly observable effects of rimonabant in Δ⁹-THC treated rodents, including paw tremors and head shaking, were attenuated not only by Δ⁹-THC, but also by clonidine (Lichtman et al., 2001), suggesting that some non-cannabinoids have therapeutic potential as treatments for marijuana withdrawal.

Drug discrimination assays have been used to characterize withdrawal from a variety of drug classes (Gellert and Holtzman, 1979; Emmett-Oglesby et al. 1990). Drug discrimination generally is highly sensitive to the effects of drugs and could be uniquely sensitive to cannabinoid withdrawal inasmuch as marijuana withdrawal in humans is evidenced primarily by symptoms (i.e., mood disturbances) and few directly observable signs (Haney et al. 1999b; Budney et al., 2004). One goal of the current study was to treat monkeys with a sufficiently large dose (1 mg/kg/12 h s.c.) of Δ⁹-THC to produce dependence and, in turn, characterize rimonabant-induced withdrawal using drug discrimination and directly observable signs. Signs measured in the present study were chosen, in part, from those reported in other species (e.g., head shaking in rodents; Cook et al., 1998) and from previous studies in rhesus monkeys. Δ⁹-THC decreased heart rate and locomotor activity in rhesus monkeys (Fredericks and Benowitz, 1980; Stark and Dews, 1980; Fredericks et al., 1981; Vivian et al., 1998); consequently, heart rate and locomotor activity were measured in the current study to examine whether rimonabant-induced withdrawal includes tachycardia and hyperactivity. To help clarify whether the effects of rimonabant during chronic Δ⁹-THC treatment were related to withdrawal, the effects of rimonabant in non-dependent monkeys were examined. Moreover, Δ⁹-THC treatment was abruptly discontinued in the current study to compare spontaneous withdrawal signs to rimonabant-induced withdrawal signs. A second goal was to examine pharmacologic manipulation of rimonabant-induced cannabinoid withdrawal. Cannabinoid agonists (CP 554940
and WIN 55212-2) were studied to examine the role of cannabinoid receptors in Δ⁹-THC withdrawal, clonidine was studied to evaluate α₂-adrenergic receptors as targets for pharmacotherapy (Lichtman et al., 2001; Haney et al., 2007), and a benzodiazepine agonist (diazepam) was studied because it reduces anxiety, a symptom of cannabinoid withdrawal (Haney et al., 1999b). Deficits in mesolimbic dopamine neurotransmission were reported in cannabinoid withdrawn animals (Diana et al., 1998); cocaine was included for study to test the hypothesis that an indirect-acting dopamine agonist attenuates cannabinoid withdrawal. The results with cocaine and diazepam demonstrate that head shaking and discriminative stimulus effects differ in their pharmacologic selectivity and sensitivity to the withdrawal-reversing effects of drugs.
METHODS

Subjects. One male and four female rhesus monkeys (*Macaca mulatta*) discriminated rimonabant (1 mg/kg i.v.) from vehicle while receiving 1 mg/kg/12 h of Δ⁹-THC s.c. Three of these monkeys previously discriminated rimonabant (1 mg/kg i.v.) from vehicle while receiving 0.32 mg/kg/day of Δ⁹-THC i.v. as described (McMahon, 2006a). Before initiating treatment with 1 mg/kg/12 h of Δ⁹-THC, treatment with the smaller dose (0.32 mg/kg/day) had been discontinued for at least one year and, during this period, the effects of rimonabant in the absence of Δ⁹-THC treatment were determined. Two other monkeys were experimentally naïve before they were treated with 1 mg/kg/12 h of Δ⁹-THC s.c. and trained to discriminate rimonabant. The five monkeys discriminating rimonabant were used to generate all of the data reported in this paper, with the exception of head shaking data measured in the absence of chronic Δ⁹-THC treatment, which was measured in a separate group of five rhesus monkeys (one female and four males) discriminating a relatively small dose (0.1 mg/kg) of Δ⁹-THC (McMahon, 2006b). In these monkeys, rimonabant-induced head shaking was measured at least 48 h after Δ⁹-THC was administered.

All monkeys were housed individually in stainless steel cages (33 inches wide x 27 inches deep x 32 inches high) on a 14-h light/10-h dark schedule (lights on at 0600 h). They were maintained at 95% free-feeding weight (range 6-11.6 kg) with a diet consisting of primate chow (Harlan Teklad, High Protein Monkey Diet, Madison, WI), fresh fruit, and peanuts, and were provided water in the home cage. Monkeys were maintained in accordance with the Institutional Animal Care and Use Committee, The University of Texas Health Science Center at San Antonio, and the Guide for the Care and Use of Laboratory Animals (National Research Council, 1996).
Surgery. Monkeys were anesthetized with ketamine (10 mg/kg i.m.) and isoflurane (1.5-3.0% inhalation). Using sterile techniques, chronic indwelling catheters (heparin coated polyurethane, od = 1.68 mm, id = 1.02 mm; Instech Solomon, Plymouth Meeting, PA) were inserted into a femoral or subclavian vein. Suture silk (coated vicryl, Ethicon Inc., Somerville, NJ) was used to anchor the catheter to the vessel and to ligate the section of the vessel proximal to the catheter insertion. The distal end of the catheter was attached to a vascular access port (Mida-cbas-c50, Instech Solomon) positioned s.c. at the mid-scapular region of the back. Telemetry transmitters (CTA-D70, Data Sciences International, St. Paul, MN) were implanted subcutaneously; a skin incision was made approximately 6 cm lateral to the abdominal midline near the flank. The skin over the flank was undermined using dissection to create a subcutaneous pocket in which the telemetry device was inserted. The skin was closed with a 3-0 absorbable nylon suture. Electrocardiogram leads were placed in line with the long axis of the heart. One electrode was placed in the upper right quadrant of the chest (just below the pectoral muscles against the rib cage near the first interspace) and the other in the lower left quadrant (interspace on the left caudal-lateral thorax).

Operant conditioning chambers. Discriminative stimulus effects and head shaking were measured concurrently in ventilated, sound-attenuating chambers in the presence of white noise. Each chamber contained two levers and two lights, one positioned above each lever. Monkeys were seated in chairs (Model R001, Primate Products, Miami, FL) and feet were placed in shoes containing brass electrodes through which a brief electric stimulus (3 mA, 250 ms) could be delivered from an a/c generator (Coulbourn Instruments, Whitehall, PA). An interface (MedAssociates, St. Albans, VT) connected the chambers to a computer, which controlled and recorded experimental events.
Discrimination training procedure. Each day Δ⁹-THC (1 mg/kg s.c.) was administered at 0600 and 1800 h and monkeys discriminated rimonabant (1 mg/kg i.v.) from vehicle (at 1200 h) under a fixed ratio 5 schedule of stimulus-shock termination. Experimental sessions consisted of consecutive, 20-min cycles. Each cycle began with a 15-min timeout; responding on the levers during the time out had no programmed consequence. The timeout was followed by illumination of red lights. The lights signaled delivery of an electric stimulus in 40 s; however, five consecutive responses on the correct lever extinguished the lights, prevented delivery of the electric stimulus, and postponed the schedule for 30 s. The correct lever was determined by administration of vehicle or rimonabant at the beginning of the session; determination of correct levers (e.g., left, vehicle; right, rimonabant) varied among monkeys and remained the same for an individual throughout the study. A response on the incorrect lever reset the response requirement on the correct lever. Response periods ended after 5 min or the delivery of four electric stimuli, whichever occurred first. Vehicle training was conducted by administering vehicle i.v. or sham (i.e., dull pressure applied to the skin overlying the vascular access port) during the first minute of each of no more than six cycles. Rimonabant training was conducted by administering the training dose (1 mg/kg i.v.) during the first minute of a cycle followed by vehicle or sham during the first minute of a second cycle. Zero to four vehicle-training cycles preceded the two rimonabant-training cycles.

Discrimination testing procedure. A monkey was tested for the first time when the following criteria were satisfied in every cycle during five consecutive or six out of seven training sessions: at least 80% of the total responses occurred on the correct lever and fewer than five responses occurred on the incorrect lever prior to completion of five consecutive responses on the correct lever. Subsequent tests were conducted when performance for consecutive
training sessions, including both vehicle and rimonabant training sessions, satisfied the criteria. The type of training session preceding test sessions varied non-systematically. Test sessions were identical to training sessions except that five consecutive responses on either lever were reinforced and animals received vehicle or a dose of drug i.v. during the first minute of a cycle.

To establish a rimonabant dose-effect curve, a dose was administered i.v. during a cycle and then vehicle or sham was administered in a second cycle. The time course of the training dose (1 mg/kg) of rimonabant was established by administering the training dose 2 and 4 h before a multiple-cycle test, during which vehicle was administered i.v. in the first cycle followed by sham in a second cycle.

To examine whether the effects of rimonabant in Δ⁹-THC treated monkeys were also observed following abrupt discontinuation of Δ⁹-THC treatment (i.e., Δ⁹-THC deprivation), multiple-cycle test sessions were conducted before, during, and after Δ⁹-THC deprivation for 6 days. Training sessions were not conducted during Δ⁹-THC deprivation. Test sessions were conducted at 1200 h and vehicle was administered i.v. in the first cycle followed by sham in subsequent cycles. The first test in the sequence was conducted during Δ⁹-THC treatment, i.e., 6 h after the morning injection of Δ⁹-THC (1 mg/kg s.c.). Monkeys were deprived of Δ⁹-THC that evening (i.e., at 1800 h) by administering vehicle s.c. instead of Δ⁹-THC and monkeys continued to receive vehicle s.c. at 0600 and 1800 h for the next five days as well as at 0600 h on the sixth and last day of Δ⁹-THC deprivation. Test sessions were conducted on days 1, 2, and 6 of the Δ⁹-THC deprivation period. On day 6 of deprivation, Δ⁹-THC treatment was resumed in the evening, i.e., monkeys received 1 mg/kg of Δ⁹-THC at 1800 h. On the following day, monkeys received 1 mg/kg of Δ⁹-THC at 0600 h and the last test of the sequence was conducted that day at 1200 h.
The effects of test compounds alone and in combination with the training dose of rimonabant were examine during 4-cycle test sessions. Vehicle or a dose of test drug was administered in the first cycle followed by sham in a second cycle; rimonabant (1 mg/kg) was administered in a third cycle followed by sham in a fourth cycle. Test drugs were Δ⁹-THC (0.32-3.2 mg/kg), CP 55940 (0.032-0.32 mg/kg), WIN 55212-2 (1-10 mg/kg), clonidine (0.0032-1 mg/kg), diazepam (0.32-3.2 mg/kg), and cocaine (0.1-1 mg/kg).

**Head shaking.** Cameras mounted inside the operant conditioning chambers provided a frontal view of each monkey. Video was record via commercially available software (GeoVision GV-650, Taipei, Taiwan) and stored on a computer. Frequency of head shaking was quantified by observers blind to treatment. Head shaking was defined as rapid, horizontal, side-to-side oscillation of the head for a minimum of 1 s. Each head shake was separated by at least 1 s of no head shaking. To establish the dose-effect curve of rimonabant and test drugs, the frequency of head shaking was measured immediately after drug administration for 40 min. To establish a time course of rimonabant in Δ⁹-THC treated monkeys, the frequency of head shaking was measured for 40 min at 2 and 4 h after administration of the training dose (1 mg/kg). To examine head shaking after abrupt discontinuation of Δ⁹-THC treatment, frequency was measured at 1200 h for 80 min. The effects of a test drug on rimonabant-induced head shaking was measured by administering the test drug 40 min before rimonabant; head shaking was measured for 40 min immediately after rimonabant was administered.

**Heart rate and activity.** Heart rate and activity were measured in four unrestrained monkeys (i.e., in the home cage) via a receiver (RMC-1, Data Sciences International), computer, and commercially available software (Dataquest Acquisition and Analysis System, Data Sciences International). Activity was defined by the position and velocity of movement of the
transmitter relative to the receiver; activity was a relative measure (i.e., more active versus less active) and not an absolute measure of distance. During a given observation period, heart rate was measured continuously for 2 min every 5 min and activity was measured continuously. The effects of vehicle and rimonabant in the absence of chronic Δ⁹-THC treatment were examined in three monkeys that had not received chronic Δ⁹-THC treatment for at least six months and in a fourth monkey that had not previously received Δ⁹-THC treatment. The effects of vehicle and rimonabant were then re-assessed in these same monkeys after they had received Δ⁹-THC (1 mg/kg/12h) for six months. Vehicle or rimonabant (0.1-3.2 mg/kg i.v.) was administered while monkeys were seated in chairs; they were immediately returned to the home cage at 1200 h for telemetry measurement. Drug discrimination sessions were not conducted on these days. Tests with different doses of rimonabant were separated by at least three days. The time course of rimonabant (1 mg/kg i.v.) on heart rate and activity was generated from a single session. For the Δ⁹-THC deprivation experiment, heart rate and activity were measured throughout the day except during discrimination test sessions (1200-1400 h).

**Drugs.** The following drugs were administered i.v.: rimonabant, Δ⁹-THC (100 mg/ml in absolute ethanol) (The Research Technology Branch, National Institute on Drug Abuse, Rockville, MD), CP 55940 (Tocris, Ellisville, MO), WIN 55212-2 and diazepam (Sigma, St. Louis, MO). For these drugs, the vehicle consisted of 1 part absolute ethanol, 1 part Emulphor-620 (Rhone-Poulenc Inc., Princeton, NJ), and 18 parts physiologic saline. Clonidine hydrochloride (Sigma, St. Louis, MO) and cocaine hydrochloride (The Research Technology Branch) were prepared in distilled sterile water and administered s.c. Ketamine hydrochloride (Bioniche, Athens, GA) was prepared in physiological saline and administered s.c. The volume was 0.03-1 ml/kg and doses (mg/kg) were expressed as the weight of the forms listed above.
**Data analyses.** Discrimination, response rate, and head shaking data were averaged from five monkeys and telemetry data (heart rate and activity) were averaged from four monkeys. Discrimination data were expressed as a percentage of responses on the rimonabant lever out of total responses on the vehicle and rimonabant levers. Rate of responding (responses per s) on both levers was converted to a control, defined as the average response rate in all cycles during the five previous vehicle-training sessions, during which the test criteria were satisfied, immediately preceding that test. Response rate data were expressed as a percentage of the control for individual animals. Discrimination data at a dose were not included for analysis or plotted when corresponding response rate was less than 20% of control in three or more subjects; however, response rate data were always included for analysis and plotted. Inter-rater reliability for measurement of head shaking was established with linear regression of frequency measured from a training database consisting of ten separate sessions. To match the temporal parameters used for measurement of head shaking (i.e., 40 min for studies with test drugs and 80 min for the Δ⁹-THC deprivation study), discrimination and response rate data were averaged from 2 and 4 cycles, respectively, for further analysis. Heart rate data were averaged from all values collected during a 40-min period and were expressed as a difference from the vehicle (non-drug) control. Activity was cumulated from all values measured for 40 min (studies with rimonabant) or for 8 h overnight (Δ⁹-THC deprivation study). For the rimonabant dose-effect and time course data as well as the Δ⁹-THC deprivation study, discrimination, response rate, head shaking, heart rate, and activity data were averaged among monkeys (± S.E.M.) and were plotted as a function of dose or time. Dose-effect and time course data were analyzed separately with ANOVA for repeated measures followed by Dunnett’s post-hoc test to examine significant differences from the vehicle control ($p < 0.05$).
Discrimination, response rate, and head shaking data after vehicle or the training dose (1 mg/kg) of rimonabant were determined in three separate test sessions; data from these tests were averaged to provide a single vehicle or rimonabant (1 mg/kg) control for further analysis with test compounds (Δ⁹-THC, CP 55940, WIN 55212-2, clonidine, diazepam, and cocaine). Head shaking data were converted to a percentage of the rimonabant control for individual subjects. Dose-effect data were analyzed separately per test compound with ANOVA for repeated measures followed by Dunnett’s post-hoc test to compare individual doses to the vehicle or rimonabant controls ($p < 0.05$).

When a drug decreased the effects of rimonabant (1 mg/kg) to less than 50%, potency was calculated by simultaneously fitting straight lines to individual dose-effect data by means of GraphPad Prism version 5.0 for Windows (San Diego, CA) with linear regression. Straight lines were fitted to the linear portion of dose-effect curves, defined by doses producing 20-80% of the maximum effect, including not more than one dose producing less than 20% of the maximum effect and not more than one dose producing greater than 80% of the maximum effect. Other doses were excluded from linear regression. The slopes of dose-effect curves were compared with an F-ratio test using GraphPad. If the slopes were not significantly different, then a common, best-fitting slope was used to calculate potency (Kenakin, 1997). Doses corresponding to the 50% level of the effect (ED₅₀), potency ratios, and their 95% confidence limits (CL) were calculated by parallel line analysis of data from individual subjects (Tallarida, 2000). Potencies were considered significantly different when the 95% confidence limits of the potency ratio did not include 1.
RESULTS

Discriminative and rate effects of rimonabant in Δ⁹-THC treated monkeys. In three monkeys previously trained to discriminate rimonabant (1 mg/kg i.v.) from vehicle in the presence of a relatively small dose (0.32 mg/kg/day i.v.) of Δ⁹-THC (McMahon, 2006a), stimulus control with rimonabant in the presence of a larger dose (1 mg/kg/12 h) of Δ⁹-THC was re-established in 8, 8, and 11 sessions in individual monkeys. For two experimentally naive monkeys, stimulus control with rimonabant (1 mg/kg i.v.) during treatment with 1 mg/kg/12 h of Δ⁹-THC was established in 30 and 53 sessions.

Rimonabant dose-dependently increased responding on the drug-appropriate lever (F₃,₁₂=142; p<0.001) (Figure 1A); doses of 0.32 and 1 mg/kg significantly increased rimonabant-lever responding to a mean of 72% and 93%, respectively. Following administration of vehicle, responding was 1% on the rimonabant lever (Figure 1A, V). The ED₅₀ value (95% confidence limits) of rimonabant to produce discriminative stimulus effects was 0.25 (0.17-0.35) mg/kg. The discriminative stimulus effects of rimonabant decreased as a function of time (Figure 1B) (F₃,₉=29.6; p<0.001), with the training dose (1 mg/kg i.v.) producing significant drug-lever responding (73%) for up to 121-160 min; percent responding on the rimonabant lever was no longer significantly different from the vehicle control at 241-280 min. Over 10 vehicle training sessions in which the criteria for testing were satisfied, average rates of lever pressing for individual monkeys were 0.70, 0.74, 0.80, 1.29, and 1.44 responses per s. Rimonabant, up to the training dose (1 mg/kg), did not significantly modify response rate (p>0.05) (Figures 1C and 1D).

The effects of rimonabant alone and during chronic Δ⁹-THC: head shaking, heart rate, and activity. The inter-rater reliability between observers measuring head shaking was
relatively high, evidenced by a coefficient of determination of 0.92; the slope of the regression line was not significantly different from unity and the intercept was not significantly different from zero. Administration of vehicle, either during chronic $\Delta^9$-THC or not, resulted in a maximum average (± S.E.M.) frequency of 1.3 (± 0.9) head shaking counts (Figure 2A, V). When administered without chronic $\Delta^9$-THC treatment, the mean frequency of head shaking following 1 and 3.2 mg/kg of rimonabant was 2.2 and 13.4, respectively (Figure 2A, filled circles). Head shaking at 3.2 mg/kg of rimonabant was due to a marked increase in two of five monkeys; the group average data were not statistically significant ($F_{2,12}=2.18; p=0.16$). During chronic $\Delta^9$-THC (1 mg/kg/12 h), rimonabant significantly increased head shaking as function of dose ($F_{3,12}=12.7; p<0.001$) (Figure 2A, open circles) and time ($F_{3,9}=9.00; p<0.01$) (Figure 2B). A dose of 1 mg/kg significantly increased head shaking frequency to 8.3 at 1-40 min, an effect that was no longer significantly different from the vehicle control at 121-160 min.

Administration of vehicle i.v. outside the home cage produced an increase in heart rate and activity when monkeys were returned to the home cage for 40 min; therefore, data were analyzed at 41-80 min, a period when heart rate and activity were no longer significantly different from data collected at the same time of day when monkeys had not been removed from the home cage. Before chronic $\Delta^9$-THC treatment, the average (± S.E.M.) vehicle control heart rate was 132.1 (± 8.1) beats per min; relatively small doses (0.32 and 1 mg/kg) of rimonabant did not significantly modify heart rate, whereas a large dose (3.2 mg/kg) of rimonabant significantly increased heart rate by 25.8 beats per min ($F_{3,9}=4.98; p<0.05$) (Figure 2C, filled circles). Relative to the non-drug control (i.e., no chronic $\Delta^9$-THC treatment), heart rate during chronic $\Delta^9$-THC (1 mg/kg/12h) was significantly decreased by 36.0 beats per min ($F_{4,12}=6.90; p<0.01$) (Figure 2C, compare open and filled circles above V). Rimonabant dose-dependently attenuated
bradycardia produced by chronic Δ⁹-THC; the significant antagonism produced by 0.32 and 1 mg/kg of rimonabant resulted in heart rate that was not different from the non-drug control (Figure 2C). Antagonism of Δ⁹-THC induced bradycardia decreased as a function of time (F₃,₉=5.36; p<0.05), i.e., antagonism produced by 1 mg/kg of rimonabant was evident at 121-160 min and not 241-280 min (Figure 2D).

The non-drug control for activity was 32, 67, 97, and 120 counts per 40-min observation period for four respective monkeys. Before chronic Δ⁹-THC, there was a tendency for rimonabant to increase activity counts, although not significantly due to relatively large error variance, i.e., average (± S.E.M.) activity after 3.2 mg/kg of rimonabant was 169 (± 58.4) counts as compared to 78.4 (± 18.6) counts after vehicle. During chronic Δ⁹-THC treatment, there was a non-significant tendency for activity to be decreased relative to the non-drug control and, further, for rimonabant to antagonize Δ⁹-THC induced hypoactivity. Mean (± S.E.M.) control activity during chronic Δ⁹-THC was 20 (± 9.7) counts, whereas activity after rimonabant (1 mg/kg) was relatively high (i.e., 72 ± 20 counts) and similar to the non-drug control.

**Temporary discontinuation of chronic Δ⁹-THC treatment.** When tested with vehicle the day before discontinuation of Δ⁹-THC treatment, responding was 0% on the rimonabant lever (Figure 3A, leftmost THC point). During the same test, response rate was 101% of control and the frequency of head shaking was 0.5 counts (Figure 3B and 3C, respectively; leftmost THC points). Upon discontinuation of Δ⁹-THC treatment, rimonabant-appropriate responding increased significantly, i.e., to 48% on deprivation day 1 (F₄,₁₆=5.93; p<0.01) (Figure 3A). Response rate during the Δ⁹-THC deprivation period was not significantly different from the pre-deprivation control (p>0.05) (Figure 3B). Head shaking frequency significantly increased during the deprivation period, to 5.3 and 8.0 counts on deprivation days 1 and 2, respectively.
(F\(_{4,16}=6.92; p<0.01\)) (Figure 3C). On deprivation day 6, head shaking was no longer significantly different from the pre-deprivation control. Upon resumption of \(\Delta^9\)-THC treatment, rimonabant-lever responding and head shaking frequency were not significantly different from pre-deprivation control values (Figure 3A and 3C, respectively; rightmost THC points), whereas response rate was significantly decreased relative to the pre-deprivation control (F\(_{4,16}=4.65; p<0.05\)), although the decrease was relatively small (Figure 3B; rightmost THC point).

During the night (i.e., 8-h period beginning 1 h after lights off and ending 1 h before lights on), mean (± S.E.M.) cumulative activity during \(\Delta^9\)-THC treatment was 0.9 (± 0.4) counts (Figure 3D, leftmost THC point). The non-drug control (i.e., no chronic \(\Delta^9\)-THC treatment) during the same 8-h period was an average (± S.E.M.) of 1.6 (± 0.4) activity counts. Upon discontinuation of chronic \(\Delta^9\)-THC treatment, night activity increased in three of four monkeys. For example, the maximum activity during any one night of the deprivation period was 16, 11, and 3.2 counts for each of three monkeys. Cumulative night activity did not vary before, during, and after the \(\Delta^9\)-THC deprivation period in one of four monkeys and analysis of the group data did not achieve statistical significance (p>0.05). Heart rate did not significantly vary as a function of \(\Delta^9\)-THC deprivation status (data not shown).

**Effects of cannabinoid agonists alone and in combination with rimonabant: discriminative stimulus effects and head shaking.** When administered alone, \(\Delta^9\)-THC (0.32-3.2 mg/kg), CP 55940 (0.032-0.32 mg/kg), and WIN 55212-2 (1-10 mg/kg) produced a maximum of 1%, 3%, and 0% responses on the rimonabant lever, respectively (Figure 4A). CP 55940 (0.32 mg/kg) and WIN 55212-2 (10 mg/kg) significantly decreased response rate to 26\% (F\(_{3,12}=11.9; p<0.001\)) and 44\% (F\(_{3,12}=6.83; p<0.01\)) of the vehicle control, respectively (Figure
4B). Δ⁹-THC, up to 3.2 mg/kg, did not significantly modify response rate. The cannabinoid agonists did not significantly increase head shaking (p>0.05) (Figure 4C).

When administered in combination with the training dose (1 mg/kg) of rimonabant, Δ⁹-THC significantly attenuated rimonabant-lever responding (F₃,₁₂=40.9; p<0.001); the effects of the training dose (92% rimonabant-lever responding) were decreased to 2% by 3.2 mg/kg of Δ⁹-THC (Figure 4D, diamonds). Likewise, the discriminative stimulus effects of rimonabant were dose-dependently attenuated by CP 55940 (F₃,₁₂=89.4; p<0.001) and WIN 55212-2 (F₃,₁₂=5.54; p<0.05) (Figure 4D, triangles and squares, respectively). However, WIN 55212-2 (up to a dose of 10 mg/kg) produced a smaller decrease (49% rimonabant-lever responding) than that obtained with 0.32 mg/kg of CP 55940 (10% rimonabant-lever responding). The slopes of the CP 55940 and Δ⁹-THC dose-effect curves were not significantly different (p>0.05) and the ED₅₀ values (95% confidence limits) were 0.14 (0.10-0.20) and 0.85 (0.66-1.1) mg/kg, respectively. CP 55940 was more potent than Δ⁹-THC, i.e., the potency ratio (95% confidence limits) was 6.0 (4.1-8.6). A slope and ED₅₀ value were not calculated for the WIN 55212-2 dose-effect data because the percentage of rimonabant-lever responding was not decreased to less than 50% in two of five monkeys. Response rate was not significantly modified when the cannabinoid agonists were combined with the training dose of rimonabant (p>0.05) (Figure 4E).

Head shaking produced by 1 mg/kg of rimonabant was significantly and dose-dependently decreased by Δ⁹-THC (F₃,₁₂=4.05; p<0.05), CP 55940 (F₃,₁₂=7.14; p<0.01), and WIN 55212-2 (F₃,₁₂=17.7; p<0.001). CP 55940 (0.32 mg/kg), Δ⁹-THC (3.2 mg/kg), and WIN 55212-2 (10 mg/kg) significantly decreased head shaking to 10%, 32%, and 18% of control, respectively (Figure 4F). The slopes of the dose-effect curves for CP 55940, Δ⁹-THC, and WIN 55212-2 were not significantly different (p>0.05); the ED₅₀ values (95% confidence limits) were
0.15 (0.07-0.33), 1.8 (0.96-3.5), and 3.0 (1.3-7.1) mg/kg, respectively. CP 55940 attenuated rimonabant-induced head shaking more potently than Δ⁹-THC and WIN 55212-2, i.e., the potency ratios (95% confidence limits) were 12 (3.1-29) and 17 (5.7-49), respectively. The potencies of Δ⁹-THC and WIN 55212-2 to attenuate head shaking were not significantly different.

**Effects of non-cannabinoids alone and in combination with rimonabant:**

**Discriminative stimulus effects and head shaking.** When administered alone, clonidine (0.0032-1 mg/kg), cocaine (0.1-1 mg/kg), and diazepam (0.32-3.2 mg/kg) produced a maximum of 26%, 39%, and 31% responding on the rimonabant lever, respectively (Figure 5A); the effect of cocaine was statistically significant (F 3,12=3.59; p<0.05) whereas the effects of clonidine and diazepam were not (p>0.05). Diazepam (3.2 mg/kg) significantly decreased response rate to 37% of the vehicle control (F 3,12=4.76; p<0.05), whereas cocaine and clonidine did not significantly modify response rate up to the largest dose (1 mg/kg) studied (p>0.05) (Figure 5B). Clonidine, cocaine, and diazepam did not significantly increase head shaking (p>0.05) (Figure 5C).

When administered in combination with the training dose (1 mg/kg) of rimonabant, drug-lever responding was dose-dependently attenuated by clonidine (F 6,18=9.18; p<0.001). The dose-effect curve for clonidine appeared to reach an asymptote with a maximum attenuation to 50% rimonabant-lever responding. Neither cocaine nor diazepam significantly attenuated the discriminative stimulus effects of rimonabant (Figure 5D, diamonds and squares, respectively). When combined with rimonabant (1 mg/kg), diazepam significantly decreased response rate to 54% and 37% of control at doses of 1 and 3.2 mg/kg, respectively (F 3,12=27.1; p<0.001).
contrast, cocaine and clonidine (up to 1 mg/kg) did not significantly modify response rate when combined with rimonabant (Figure 5E).

Rimonabant-induced head shaking was dose-dependently attenuated by clonidine ($F_{6,18}=7.46; p<0.001$) and cocaine ($F_{3,9}=23.4; p<0.001$) (Figure 5F). Although ANOVA of the diazepam dose-effect data was not statistically significant ($p>0.05$), diazepam decreased rimonabant-induced head shaking to less than 50% of control in all five monkeys. Furthermore, linear regression demonstrated that the effects of diazepam were dose-dependent (i.e., the slope of the dose-effect curve was significantly different from 0). The slopes of the clonidine, cocaine, and diazepam dose-effect curves to attenuate rimonabant-induced head shaking were not significantly different ($p>0.05$). The ED$_{50}$ values (95% confidence limits) were 0.01 (0.003-0.03) mg/kg for clonidine, 0.59 (0.28-1.2) mg/kg for cocaine, and 1.4 (0.41-5.4) mg/kg for diazepam. Clonidine was significantly more potent than cocaine and diazepam, which were equipotent.
DISCUSSION

Rhesus monkeys receiving chronic $\Delta^9$-THC (1 mg/kg/12 h) treatment reliably discriminated the cannabinoid antagonist rimonabant (1 mg/kg). Rimonabant had similar potency for producing discriminative stimulus effects, head shaking, and antagonism of $\Delta^9$-THC induced bradycardia. In the absence of chronic $\Delta^9$-THC treatment, a relatively large dose (3.2 mg/kg) of rimonabant produced tachycardia and tended to increase head shaking. When $\Delta^9$-THC treatment was abruptly discontinued, there was an increase in both rimonabant-lever responding and head shaking. Moreover, activity during the night, which was typically low in the absence of any drug treatment, tended to increase in monkeys deprived of chronic $\Delta^9$-THC treatment. The rimonabant discriminative stimulus was attenuated fully by $\Delta^9$-THC and CP 55940 and partially by WIN 55212-2 and clonidine; diazepam and cocaine did not attenuate the rimonabant discriminative stimulus. In contrast, rimonabant-induced head shaking was non-selectively attenuated by the test compounds. These results show that the discriminative stimulus effects of rimonabant in $\Delta^9$-THC treated monkeys are a more pharmacologically selective measure of cannabinoid withdrawal than rimonabant-induced head shaking. In addition to cannabinoid agonists, $\alpha_2$-adrenergic agonists appear to be potential pharmacotherapies for treating marijuana withdrawal.

Rhesus monkeys were dependent on $\Delta^9$-THC, evidenced by increases in rimonabant-lever responding, head shaking, and night activity when $\Delta^9$-THC treatment was abruptly discontinued. The magnitude of rimonabant-lever responding obtained following abrupt discontinuation of $\Delta^9$-THC treatment did not achieve the same maximum produced by the training dose of rimonabant during $\Delta^9$-THC treatment, suggesting that withdrawal upon abrupt discontinuation of treatment was less robust than rimonabant-induced withdrawal. This result is consistent with previous
studies assessing signs of cannabinoid withdrawal in rodents (Aceto et al., 1996), and with drug discrimination studies showing that withdrawal induced by abrupt discontinuation of opioid treatment was less robust than antagonist-induced opioid withdrawal (Gellert and Holtzman, 1979). Slow metabolism and elimination of Δ⁹-THC and its active metabolites (Grotenhermen, 2003) could decrease withdrawal magnitude, as has been shown for other drug classes (i.e., long-acting barbiturates; Boisse and Okamoto, 1978). The presently used dose (1 mg/kg/12 h) of Δ⁹-THC was comparable to that used previously to produce dependence in rhesus monkeys (Fredericks and Benowitz, 1980), evidenced in one study by a disruption in food-maintained responding when Δ⁹-THC treatment was abruptly discontinued (Beardsley et al., 1986). That operant responding was not disrupted in the current study might have been due to the reinforcer (stimulus-shock termination) or route of chronic Δ⁹-THC treatment (s.c.), which differed from those (food presentation and i.v.) used in the previous study (Beardsley et al., 1986). The current study is the first to indicate that head shaking is a sign of cannabinoid withdrawal in primates. Sleep disruption, a prominent sign of marijuana withdrawal in humans (Haney et al. 1999a; 1999b; Budney et al., 2004), seems likely responsible for the increased night activity in three of four rhesus monkeys deprived of chronic Δ⁹-THC in the current study.

Rimonabant-induced cannabinoid withdrawal in primates was evidenced by dose-dependent and reliable discriminative stimulus effects and head shaking. Several lines of evidence suggest that discriminative stimulus effects measured here reflected rimonabant-induced Δ⁹-THC withdrawal. First, in the absence of chronic Δ⁹-THC treatment, rimonabant could not be trained as discriminative stimulus in rhesus monkeys up to a training dose of 3.2 mg/kg i.v. (McMahon, 2006a). Second, the ED₅₀ value for the discriminative stimulus effects of rimonabant was strikingly similar to the apparent affinity (pA₂) or dose of rimonabant occupying
50% of cannabinoid receptors, as determined from antagonism of the discriminative stimulus effects of cannabinoid agonists (McMahon, 2006b). The ED$_{50}$ value of the rimonabant discriminative stimulus also was comparable to doses of rimonabant that antagonized Δ$^9$-THC induced bradycardia, which was evident even after six months of Δ$^9$-THC treatment (see also Kaymakcalan and Sivil, 1974; Fredericks et al., 1981). Third, rimonabant had the same potency for producing discriminative stimulus effects and a sign of withdrawal (head shaking). The discriminative stimulus effects of rimonabant under the present experimental conditions appear to be related to Δ$^9$-THC dependence and withdrawal.

Head shaking was evident not only when rimonabant (1 mg/kg) was administered during Δ$^9$-THC treatment, but also when Δ$^9$-THC treatment was abruptly discontinued, demonstrating that head shaking is a cannabinoid withdrawal sign. However, in the absence of chronic Δ$^9$-THC, a relatively large dose (3.2 mg/kg) of rimonabant produced tachycardia and head shaking, although the latter was not statistically significant. If rimonabant-induced head shaking in Δ$^9$-THC treated monkeys is a withdrawal sign, then antagonism of Δ$^9$-THC must be the underlying mechanism. In contrast, rimonabant-induced head shaking and tachycardia in the absence of Δ$^9$-THC treatment could be due to a variety of mechanisms; for example, rimonabant is a CB$_1$ receptor inverse agonist in vitro (Bouaboula et al., 1997). A previous study demonstrated that chronic treatment with a benzodiazepine agonist increased sensitivity to convulsions produced by benzodiazepine inverse agonists (Sannerud et al., 1991). Chronic Δ$^9$-THC treatment increased sensitivity to rimonabant-induced head shaking in monkeys (present study) and rodents (Cook et al., 1998), perhaps implicating CB$_1$ inverse agonism as the mechanism by which rimonabant produces behavioral effects in the absence of Δ$^9$-THC treatment. Alternatively, the behavioral effects of rimonabant could be due to antagonism of endogenous cannabinoid
neurotransmitters (anandamide and 2-AG). However, the apparent affinity of rimonabant determined in the presence of anandamide and Δ⁹-THC was similar (McMahon, 2008), suggesting that rimonabant should have similar potency for producing behavioral effects regardless of whether antagonism of anandamide or Δ⁹-THC is the underlying mechanism. The apparent affinity of rimonabant in the presence of other endocannabinoids (2-AG) has not been determined; to the extent that rimonabant antagonizes 2-AG with a lesser potency than that for other agonists, antagonism of 2-AG could be responsible for the effects of rimonabant alone. In Δ⁹-THC treated monkeys, rimonabant-induced head shaking was attenuated by every test compound (cannabinoid, α₂-adrenergic, benzodiazepine, and monoamine agonists) included for study. Even though head shaking appears to be a cannabinoid withdrawal sign, its utility for establishing the neuropharmacology of cannabinoid dependence and withdrawal is limited by a lack of pharmacologic selectivity.

If the discriminative stimulus effects of rimonabant in Δ⁹-THC treated animals were related to withdrawal, then attenuation would be expected from increasing the dose of the dependence-inducing drug (Δ⁹-THC), which was demonstrated here. Furthermore, to the extent that cannabinoid agonism is the mechanism by which Δ⁹-THC attenuates rimonabant-induced withdrawal, other cannabinoid agonists would also be expected to attenuate withdrawal, which was demonstrated here (i.e., CP 55940). Although CP 55940 was more potent than Δ⁹-THC, their individual potencies were similar with respect to attenuation of rimonabant-induced head shaking and discriminative stimulus. In contrast, the potency of WIN 55212-2 varied across the two measures, which can be illustrated by comparing the relative potency of WIN 55212-2 and Δ⁹-THC. For example, WIN 55212-2 was less potent than Δ⁹-THC in attenuating the discriminative stimulus effects of rimonabant, whereas the agonists were equipotent in reducing
rimonabant-induced head shaking. In monkeys discriminating a relatively small dose of Δ⁹-THC, the potencies of Δ⁹-THC and WIN 55212-2 also were similar (McMahon, 2006b). Moreover, in that previous study, surmountable antagonism of Δ⁹-THC was observed across a broader range of doses of rimonabant than antagonism of WIN 55212-2 (McMahon, 2006b). Collectively, these results show that Δ⁹-THC and WIN 55212-2 differ in their interaction with rimonabant and suggest that Δ⁹-THC and WIN 55212-2 differ in receptor mechanism of action; one interpretation is that WIN 55212-2 acts via rimonabant-sensitive (CB₁) and -insensitive (non-CB₁) receptors. Head shaking was a less pharmacologically selective measure of the effects of rimonabant than discriminative stimulus effects; therefore, a drug acting at both CB₁ and non-CB₁ receptors (WIN 55212-2) might be relatively more potent at attenuating the former (i.e., less pharmacologically selective measure) as compared to attenuation of the latter. With regard to therapeutic potential, the current results suggest that attenuation of Δ⁹-THC or marijuana withdrawal by cannabinoid agonists varies according to the relative activity at CB₁ versus other receptors.

A therapeutic with a mechanism of action distinct from marijuana (i.e. a non-cannabinoid) might have some advantages over marijuana-like compounds in marijuana-dependent individuals. Cross-tolerance from marijuana to a non-cannabinoid, for example, should be less than cross-tolerance to a cannabinoid. Moreover, a non-cannabinoid would be expected to not have marijuana-like abuse and dependence liability. In the current study, a benzodiazepine (diazepam) did not attenuate the rimonabant discriminative stimulus, suggesting that anxiolytic activity is not sufficient to attenuate this particular measure of Δ⁹-THC withdrawal. In contrast, the α₂-adrenergic agonist clonidine attenuated the rimonabant discriminative stimulus, although attenuation by clonidine was partial (i.e., achieved an
asymptote at 50%). Although clonidine was less effective than Δ⁹-THC and CP 55940, clonidine has relatively low abuse liability (Roehrich and Gold, 1987), which might increase the potential therapeutic utility of α₂-adrenergic agonists for marijuana dependence. The present results are consistent with the results of a clinical study reporting that the α₂-adrenergic agonist lofexidine attenuated marijuana withdrawal (Haney et al., 2007). In that clinical study, lofexidine was effective when combined with Δ⁹-THC. Further studies are needed to help determine whether cannabinoid and α₂-adrenergic agonists have greater therapeutic utility when they are combined as compared to when they are administered separately. The rimonabant discriminative stimulus in Δ⁹-THC treated monkeys appears be an appropriate pre-clinical measure of cannabinoid withdrawal, and might be an especially useful measure of the subjective experience of cannabinoid withdrawal. Studies with cannabinoid and α₂-adrenergic agonists, alone and in combination, as well as studies with novel classes of drugs in this assay have the potential to identify not only the neurobiological underpinnings of cannabinoid dependence, but also medicines that could help marijuana-dependent individuals achieve abstinence.
