Abstract

The most common cause of inherited mental retardation, Fragile X Syndrome (FXS), results from a triplet repeat expansion in the FMR1 gene and loss of the mRNA binding protein, fragile X mental retardation protein (FMRP). In the absence of FMRP, signaling through Group I metabotropic glutamate receptors (mGluRs) is enhanced. We previously proposed a mechanism whereby the audiogenic seizures exhibited by FMR1 null mice result from an imbalance in excitatory mGluR and inhibitory GABA_B receptor signaling (Pacey et al., 2009). Here we tested the mGluR5 positive allosteric modulator CDPPB, the mGluR5 inverse agonist MPEP, and GABA_B receptor agonists, alone and in combination on receptor protein expression and audiogenic seizures in FMR1 mice. Single doses of MPEP (30 mg/kg), the GABA_B orthosteric agonist R-baclofen (1 mg/kg), or the GABA_B positive allosteric modulator GS-39783 (30 mg/kg), reduced the incidence of seizures. However, when administered subchronically (daily injections for 6 days), MPEP retained its anticonvulsant activity while R-baclofen and GS-39783 did not. When administered at lower doses that had no effect when given alone, a single injection of MPEP plus R-baclofen also reduced seizures, but the effect was lost after subchronic administration. Surprisingly, subchronic treatment with R-baclofen also induced tolerance to a single high dose of MPEP. These data demonstrate that tolerance develops rapidly to the anti-seizure properties of R-baclofen alone and R-baclofen co-administered with MPEP, but not with MPEP alone. Our findings suggest that cross-talk between the G-protein signaling pathways of these receptors affects drug efficacy after repeated treatment.
Introduction

Fragile X Syndrome (FXS) is caused by the expansion of a CGG triplet repeat in the 5’ untranslated region of the FMR1 gene which induces silencing of gene expression and the absence of the mRNA-binding protein Fragile X Mental Retardation Protein (FMRP). The “mGluR Theory of Fragile X” (Bear et al., 2004) postulates that, in the absence of FMRP, protein translation downstream of Group I metabotropic glutamate receptors (mGluRs) is abnormal, leading to enhanced mGluR signaling which contributes to many of the phenotypes associated with FXS. The mGluR theory also suggests that reducing Group I mGluR (mGluR1 and mGluR5) signaling should alleviate some of the symptoms of FXS (Bear, 2005). Indeed, treatment with mGluR5 antagonists has been shown to reduce seizures and hyperactivity in FMR1 KO mice (Yan et al., 2005), restore dendritic spine defects in cultured neurons lacking FMRP (de Vrij et al., 2008) and correct behavioral deficits in FMR1 null flies (McBride et al., 2005). Genetic reduction of mGluR5 expression in mice also rescues several FXS phenotypes including abnormal ocular dominance plasticity, increased protein synthesis, seizures and spine defects (Dolen et al., 2007).

While much focus has been placed on Group I mGluRs, evidence for changes in the GABAergic system in FXS has emerged, and both Group I mGluR antagonists and GABAB receptor agonists are being tested in clinical trials of FXS (see Hampson et al., 2011 for a review). GABA exerts its effects through two distinct families of receptors. The ionotropic GABA_A receptors are pentameric chloride channels that mediate fast inhibition through controlling the movement of chloride across the cell membrane, while metabotropic GABA_B receptors are heteromeric G-protein coupled receptors that require dimerization of the R1 and R2
subunits in order to form fully functional receptors. GABA_B receptors are localized pre- or postsynaptically where they mediate slow inhibition through G_\alpha-mediated inhibition of adenylyl cyclase and/or activation of inwardly-rectifying K+ channels (GIRKs). Presynaptic GABA_B receptors also regulate the release of glutamate (Vigot et al., 2006).

Decreased GABA_A receptor expression and function has been demonstrated in FMR1 knockout mice (El Idrissi et al., 2005; D'Hulst et al., 2006; Curia et al., 2009; D'Hulst et al., 2009; Adusei et al., 2010; Olmos-Serrano et al., 2010). We have also recently demonstrated that GABA_BR1 expression is down-regulated in the forebrains of immature and mature FMR1 mice compared to wild-type mice (Pacey et al., 2011). This observation is particularly interesting because GABA_B receptor expression has also been reported to be reduced in the brains of persons with autism, a disorder related to FXS (Fatemi et al., 2009). However, other studies conducted on FMR1 mice showed increased sensitivity to the locomotor suppressing effects of the orthosteric GABA_B receptor agonist R/S-baclofen (Zupan and Toth, 2008), and treatment with R-baclofen prevents audiogenic seizures in these mice (Pacey et al., 2009). Additionally, increased GABA_B signaling is at least partially responsible for the rescue of audiogenic seizures in FMR1 mice lacking Regulator of G-protein Signaling 4 (RGS4, a protein that normally inhibits GABA_BR signaling; Pacey et al., 2009; Pacey et al., 2011). Finally, drugs that increase GABA signaling rescued diet-induced glutamate lethality in FMR1 null flies (Chang et al., 2008). Taken together, these findings point to the GABAergic system as a promising pharmacological target for treating FXS.

The purpose of the present study was three-fold. The first goal was to investigate the effectiveness of a combination of MPEP and R-baclofen at low doses that did not block seizures in FMR1 mice when given individually. The second objective was to examine both receptor
subunit expression and seizure susceptibility after subchronic administration (6 days) of MPEP, R-baclofen, and combinations of the two drugs. The third objective was to examine the effects of the mGluR5 positive allosteric modulator CDPPB and the GABA<sub>B</sub> receptor positive allosteric modulator GS-39783 on audiogenic seizures. We found that the combination of a low dose of MPEP together with a low dose of R-baclofen was effective in suppressing seizures in FMR1 mice after a single treatment, but that tolerance to the anti-seizure effects of GABA<sub>B</sub> receptor agonists and a combination of GABA<sub>B</sub> receptor agonist plus MPEP became apparent after short-term treatment. These findings have implications for the treatment of FXS and possibly for related conditions such as autism spectrum disorders.

**Methods**

**Animals**

All animal experiments were carried out in accordance with the guidelines set out by the Canadian Council on Animal Care and were approved by the University of Toronto Animal Care Committee. FMR1 knockout mice (backcrossed >10 generations on the C57BL/6 background) were generously provided by Dr. William Greenough, University of Illinois, and bred at the University of Toronto. All mice were the off-spring of homozygous pairings.

**Audiogenic seizure testing and drug injections**

Audiogenic seizure testing was carried out as previously described (Pacey et al., 2009). Briefly, FMR1 knockout mice (27-30 days old) were placed individually into the testing apparatus and were allowed to explore for 2 minutes, after which the 135db bell was rung for 2 minutes. Animals were tested only once. Seizure testing was carried out between 1:00 p.m. and
6:00 p.m. Seizure activity was observed and scored using a seizure severity score as follows: Wild running = 1; clonic seizure = 2; tonic seizure = 3; status epilepticus/respiratory arrest/death = 4 (Musumeci et al., 2000). For the data analyses the animals that obtained a score of 0 or 1 were classified as “no seizures” while animals with a score of 2 or more were considered as having seizures. Seizure incidence for drug injected animals was compared to the appropriate vehicle and Fisher’s Exact test was used for statistical analysis of seizure susceptibility incidence.

For drug injection studies, an intraperitoneal (i.p.) or subcutaneous (s.c.) injection of drug or vehicle (0.1mL/10g body weight) was administered 60 minutes prior to seizure testing (“acute treatment”) or daily for six days beginning on postnatal day (PND) 25 (“subchronic treatment”) with the final injection 60 minutes before testing on PND30. For subchronic administration, mice were injected between 2 and 4 pm daily. The drugs and vehicles were as follows: R-baclofen (Tocris Bioscience), MPEP (2-Methyl-6-(phenylethynyl)pyridine hydrochloride; FRAXA foundation), CGP 46381 ((3-Aminopropyl) (cyclohexylmethyl) phosphinic acid; Tocris Bioscience) in 20% β-cyclodextrin (Sigma); GS-39783 (N,N'-Dicyclopentyl-2-(methylthio)-5-nitro-4,6-pyrimidine diamine; Tocris Bioscience) suspended in 10% polyethylene glycol 200/15% DMSO/75% sterile saline. CDPPB (3-Cyano-N-(1,2 diphenyl-1H-pyrazol-5-yl) benzamide; Tocris Bioscience) suspended in 50% DMSO/ 50% sterile saline.

**Western blotting**
Immediately after seizure testing, mice were euthanized with an overdose of ketamine/xylazine and the brains removed and frozen on dry ice. Quantitative western blotting was performed on whole forebrain homogenates as previously described (Adusei et al., 2010). The following antibodies were used: mouse anti-GABA\textsubscript{B}R1 (clone NR3A/49; 1:250; NeuroMab, University of California, Davis/NIH), mouse anti-GABA\textsubscript{B}R2 (clone N81/2; 1:750; NeuroMab, University of California, Davis/NIH), rabbit anti-mGluR5 (1:500; Chemicon) and mouse anti-GAPDH antibody (1:40,000-1:100,000; Sigma) and a goat anti-mouse (Jackson Labs) or goat anti-rabbit (Pierce) HRP-conjugated secondary antibody. The immunoreactive proteins were visualized using the FluorChem™ MultiImage Light Cabinet (Alpha Innotech). Densitometric analysis was carried out using the AlphaEaseFC software (Alpha Innotech). The intensity of the band of interest was normalized relative to the GAPDH band intensity. Protein expression in drug treated animals is presented as a percentage of expression in vehicle controls. An unpaired student t test was used to determine statistical significance.

Results

Acute administration of MPEP, R-baclofen or GS-39783 reduced seizures in FMR1 mice

FMR1 knockout mice are susceptible to audiogenic seizures (Chen and Toth, 2001). Since the incidence of audiogenic seizures is very low (~5%) in wild-type C57BL/6 mice (Pacey et al., 2009), only FMR1 knockout mice were used in this study. Single injections of MPEP (Yan et al., 2005) and R-baclofen (Pacey et al., 2009) have been previously shown to reduce the incidence of audiogenic seizures in FMR1 mice. To confirm these results, FMR1 mice were treated with 30 mg/kg MPEP or 1mg/kg R-baclofen 60 minutes before seizure testing (Fig. 1A). Vehicle treated FMR1 mice had a seizure incidence of 60%. Both 30mg/kg MPEP and 1 mg/kg
R-baclofen significantly reduced seizure incidence to 13% (p = 0.03 compared to vehicle). The GABA<sub>B</sub> receptor positive allosteric modulator GS-39783 was also tested for its anti-seizure capabilities. GS-39783 (30 mg/kg) reduced seizures in FMR1 mice to 25% compared to vehicle controls (10% PEG/15% DMSO/75% saline), which had a seizure rate of 69%, although this difference did not quite reach statistical significance (Fig. 1A, p = 0.054).

FMR1 mice develop tolerance to R-baclofen and GS-39783 but not MPEP after repeated administration

Next we determined whether these drugs could maintain their anti-convulsant activities after subchronic administration. FMR1 mice were injected with MPEP (30 mg/kg), R-baclofen (1 mg/kg), GS39783 (30 mg/kg), or vehicle daily for 6 days beginning on postnatal day (PND) 25. Seizure testing was carried out 60 minutes after the final injection on PND30. After subchronic administration, 82% of vehicle treated mice had seizures (note that the seizure incidence in the vehicle group was consistently higher after subchronic administration as compared to a single injection), while none of the eight animals treated with 30 mg/kg MPEP had seizures (p = 0.0007, Fig. 1B). This indicated that MPEP retained its anticonvulsant activity after sub-chronic administration. In contrast, the anticonvulsant efficacy of R-baclofen and GS-39783 was reduced after subchronic administration compared with single drug injections (Fig. 1B), with 50% and 38% of animals exhibiting seizures respectively, compared to controls after 6 daily injections (p = 0.32 and 0.18 respectively compared to vehicle).

Acute administration of a combination of low dose MPEP and R-baclofen prevents seizures in FMR1 KO mice
Given that targeting mGluR5 or GABAB receptors alone can alleviate seizures in FMR1 mice, we postulated that treating mice with combined low doses of MPEP and R-baclofen should also reduce seizures and that using low doses of both drugs might prevent the tolerance seen with the high dose of R-baclofen. Treatment with 10 mg/kg MPEP alone or 0.5 mg/kg R-baclofen alone did not significantly affect the incidence of audiogenic seizures compared to vehicle controls (67% seizures for MPEP or R-baclofen alone; 60% seizures for vehicle; Fig. 2A). However, when animals were treated simultaneously with a combined dose of 10 mg/kg MPEP plus 0.5 mg/kg R-baclofen the incidence of seizures dropped to 17% (p = 0.03 compared to vehicle). This finding demonstrates that low doses of MPEP and R-baclofen that are not anticonvulsant when administered alone, can significantly reduce seizure activity when administered in combination. This finding supports the theory that an imbalance in mGluR and GABAB receptor signaling contributes to audiogenic seizures in FMR1 null mice.

**FMR1 mice develop tolerance to combined low dose MPEP plus R-baclofen after repeated administration**

We also tested whether the combination of 10 mg/kg MPEP plus 0.5 mg/kg R-baclofen maintained its anticonvulsant activity after repeated administrations (Figure 2B). Similar to a single injection, 6 daily injections of either 10 mg/kg MPEP or 0.5 mg/kg R-baclofen alone did not affect seizure incidence with 89% and 78% of animals exhibiting seizures respectively, compared to 88% of vehicle controls (p = 1.0 and 1.0 respectively). Surprisingly, the combination of 10 mg/kg MPEP plus 0.5 mg/kg R-baclofen no longer prevented seizures after repeated injections, with 78% of animals exhibiting seizures (p = 1.0).
mGluR5 and GABA<sub>B</sub> receptor expression after repeated administration of MPEP, R-baclofen and GS-39783

mGluR5 and GABA<sub>B</sub> receptor subunit expression was examined in the forebrains of mice treated subchronically with 30 mg/kg of MPEP, 1 mg/kg of R-baclofen, or 30 mg/kg of GS-39783. Western blot analysis indicated that there was no difference in mGluR5 expression in the brains of FMR1 mice treated sub-chronically with 30 mg/kg MPEP compared to vehicle controls (103.4 ± 7.0% of vehicle; p > 0.05; Fig 3C). Subchronic treatment with R-baclofen induced a small, non-significant decrease in GABA<sub>B</sub>R1 (80.4 ± 4.7% of vehicle, p > 0.05) and GABA<sub>B</sub>R2 (90.2 ± 5.6%; p > 0.05; Fig 3B) compared to vehicle controls. Interestingly, mice treated with GS-39783 displayed a dramatic reduction in GABA<sub>B</sub> receptor expression in the forebrain compared to vehicle treated mice (GABA<sub>B</sub>R1, 65.7 ± 6.9% of vehicle, p < 0.05; GABA<sub>B</sub>R2, 52.6 ± 3.6%; p < 0.001; Fig 3A). An analysis of R-baclofen and GS-39783 treated animals was performed to determine whether GABA<sub>B</sub> receptor expression might correlate with seizure incidence. However, there was no significant difference in GABA<sub>B</sub>R1 or R2 expression in the brains of mice that had seizures compared to those that did not have seizures after treatment with either R-baclofen or GS-39783 (data not shown).

mGluR5 and GABA<sub>B</sub> receptor expression was also examined in the forebrains of mice treated subchronically with low dose MPEP (10 mg/kg) and R-baclofen (0.5 mg/kg) alone and in combination. Western blot analysis demonstrated no difference in GABA<sub>B</sub> receptor expression after treatment with low dose R-baclofen (Fig. 4C and D; R1 expression 116.7 ± 30.7% of vehicle; R2 expression 94.0 ± 11.8% of vehicle; p > 0.05 for both). Surprisingly, treatment with the low dose MPEP induced a significant reduction in mGluR5 expression after subchronic treatment (Fig. 4A and B; 70.7 ± 6.1% of vehicle, p < 0.01). Although this result was
unexpected given that MPEP is an mGluR5 inverse agonist, it is consistent with the findings of Cowen et al. (2005) who demonstrated a decrease in mGluR5 expression in the olfactory tubercle of rats treated for 12 days with the structurally similar mGluR5 antagonist MTEP. As observed with subchronic treatment with low dose MPEP alone, subchronic treatment with low dose MPEP plus R-baclofen also reduced expression of mGluR5, although in this case the reduction was not statistically significant (88.8 ± 15.9%, p > 0.05). The combination treatment also did not produce significant changes in GABA_B R1 or R2 subunit expression compared to vehicle-treated mice (Fig. 4E and F; R1 expression 125.2 ± 24.6% of vehicle; R2 expression 107.0 ± 5.8% of vehicle; p > 0.05 for both).

**Acute and subchronic administration of the mGluR5 positive modulator CDPPB**

Based on our theory that audiogenic seizures result from an imbalance in Group I mGluR and GABA_B receptor signaling, we predicted that reducing GABA_B receptor signaling might negate the anti-convulsant effect of MPEP. To test this, FMR1 mice were treated with 30 mg/kg MPEP and 60 mg/kg of the GABA_B antagonist CGP46381 60 minutes before seizure testing (Fig. 5A). Treatment with CGP46381 alone exacerbated seizures in FMR1 mice (100% seizures with CGP46381; p = 0.039 vs. vehicle) whereas the seizure incidence after treatment with MPEP plus CGP46381 was not significantly different from vehicle (27% seizure incidence; p = 0.15 compared to vehicle) indicating that CGP46381 reduced the effectiveness of MPEP in alleviating audiogenic seizures.

We also tested whether treatment with the mGluR5 positive allosteric modulator CDPPB could counteract the anti-convulsant effects of R-baclofen. Interestingly, treatment with 30 mg/kg CDPPB alone did not exacerbate seizure activity but instead completely blocked seizures (0% seizures with CDPPB; p = 0.002 vs. vehicle; Fig 5B). The seizure incidence after the
combined treatment with 30 mg/kg CDPPB with 1mg/kg R-baclofen (37%) was not different from vehicle (p = 0.29) indicating that the combination of a mGluR5 positive modulator plus GABA\textsubscript{B} agonist was less effective in preventing seizures than either drug administered alone. A lower dose of CDPPB (10 mg/kg) administered alone had no effect on seizure incidence (43% seizure incidence; p = 0.44 compared to vehicle), while 10 mg/kg CDPPB administered with 1 mg/kg R-baclofen significantly reduced the incidence of seizures (0%) compared to vehicle (p = 0.02; Fig. 5B).

We were intrigued by the finding that a high dose of the mGluR5 positive allosteric modulator CDPPB blocked seizures in FMR1 KO mice when administered acutely. To determine whether this effect persisted after repeated administrations, we treated FMR1 mice for six days with 30 mg/kg CDPPB and tested for seizures one hour after the final dose. After subchronic treatment, 63% of the mice had seizures, which was not different from vehicle (83% seizure incidence; p = 0.58, Figure 6A); this indicated that tolerance developed to the anti-convulsant effects of CDPPB after 6 days of administration. The levels of mGluR5 protein in the forebrains of mice injected subchronically with CDPPB was measured by quantitative western blot (Figure 6B and C); there was a trend towards decreased mGluR5 expression in FMR1 mice (74.7 ± 4.8% of vehicle; p = 0.056). Interestingly, subchronic injection of vehicle or 30 mg/kg CDPPB did not induce seizures in wild-type mice (data not shown) and no changes in mGluR5 expression were detected in the forebrains of CDPPB-injected wild-type animals when compared to vehicle controls (105.5 ± 9.0% of vehicle; p = 0.62, Fig. 6B and C).

**Subchronic administration of low dose R-baclofen modifies the response of FMR1 mice to a high dose of MPEP**
In a final series of experiments, mice were treated for 5 days (PND25-29) with low doses of MPEP (10 mg/kg) or R-baclofen (0.5 mg/kg), alone or in combination, followed by a single high dose of MPEP (30 mg/kg) 1 hour before testing on PND30. In mice pre-treated with only the low dose MPEP, a single high dose of MPEP still blocked seizures (0% seizure incidence vs. 88% in vehicle-treated; p = 0.005; Fig. 7). Surprisingly, when mice were pre-treated with a combination of low dose MPEP plus low dose R-baclofen for 5 days, a single injection of 30 mg/kg MPEP was no longer effective in preventing seizures (86% seizure incidence; p = 1.00 vs. vehicle). Moreover, pre-treatment for 5 days with low dose R-baclofen alone also produced tolerance to the anti-seizure effects of high dose MPEP (57% seizure incidence; p = 0.28 vs. vehicle). These results indicate that subchronic treatment with a low dose of R-baclofen can modulate the response to MPEP suggesting cross-talk between the GABA<sub>B</sub> and mGluR5 pathways.

**Discussion**

Our results show that when administered as single doses, MPEP (30 mg/kg), R-baclofen (1 mg/kg) and the GABA<sub>B</sub> positive modulator GS-39783 (30 mg/kg) displayed robust suppression of audiogenic seizures in FMR1 mice. However, when FMR1 mice were treated daily for 6 days, MPEP retained its anti-convulsant activity while R-baclofen and GS-39783 did not. Baclofen has previously been shown to induce tolerance in several models of chronic pain (Lehmann et al., 2003; Sands et al., 2003) and in humans after intrathecal infusion (Akman et al., 1993; Nielsen et al., 2002). In the present study, western blot analysis showed no significant difference in GABA<sub>B</sub> receptor expression in the forebrains of FMR1 mice after subchronic treatment with R-baclofen. This is consistent with previous findings suggesting that baclofen
induces tolerance through mechanisms other than down-regulation of GABA_B receptor expression (Lehmann et al., 2003; Sands et al., 2003). However, it is possible that microdissection and analysis of specific brain regions (e.g. the inferior colliculus, a brain region that may mediate audiogenic seizures) might have demonstrated regional changes in GABA_B receptor expression after baclofen injection.

We initially hypothesized that targeting GABA_B receptors with GS-39783, a positive allosteric modulator, rather than an orthosteric agonist (R-baclofen), might provide a better long-term approach given the overall theoretical advantages of using allosteric modulators as therapeutic drugs (Keov et al., 2011; Gregory et al., 2011), and the specific observations that GS-39783 has been shown to produce fewer side effects (Cryan et al., 2004) and less tolerance (Mombereau et al., 2004) after repeated administration in mouse models of anxiety. In addition, Gjoni and Urwyler (2008) demonstrated that prolonged administration of GS-39783 did not lead to GABA_B receptor desensitization in cultured cells. However, in the present study, GS-39783 produced tolerance in FMR1 mice, with an accompanying decrease in GABA_B receptor levels. The differences between our results examining the effects of GS-39783 on seizures in FMR1 mice and those of Mombereau et al., (2004) who studied the effects of this drug in tests of anxiety and depression in GABA_B R1 null mice may be due to differences in the strain of mice used (C57/BL6 vs. BALB/c), route of administration (i.p. vs. oral), length of treatment time (6 days vs. 21 days), and the doses used (30 mg/kg in the present study vs. 0.3 – 30 mg/kg in Mombereau et al.). In our experiments, doses of GS-39783 below 30 mg/kg were tested but appeared to have minimal efficacy in blocking seizures.

Based on the efficacy of both mGluR antagonists and GABA_B agonists in reducing audiogenic seizures after single administrations, we hypothesized that a combination of low
doses of MPEP and R-baclofen might prevent seizures while also avoiding the adverse side-effects and tolerance seen with higher doses of baclofen. When administered acutely, a combination of MPEP plus R-baclofen prevented seizures; however, the effect was lost after repeated administration. A possible explanation for this finding is that, when administered acutely, baclofen might preferentially target presynaptic GABA_{B} receptors to reduce glutamate release thus reducing mGluR5 stimulation and relieving audiogenic seizures. However, after repeated administrations, GABA_{B}R desensitization occurs (which may or may not be accompanied by changes in receptor expression) and glutamate release is no longer blocked, thus restoring enhanced mGluR5 signaling and seizures in FMR1 mice. When low doses of MPEP and R-baclofen are combined, the additive effect of reduced glutamate release and decreased mGluR5 activation is responsible for alleviating seizures. We hypothesize that tolerance occurs after repeated administration due to the loss of the GABA_{B}-mediated reduction in glutamate release, since the receptor blockade induced by the low dose of MPEP alone is not sufficient to prevent seizures. Further experiments are needed to examine this hypothesis.

Our data also demonstrate that R-baclofen promotes tolerance to the anti-convulsant effects of MPEP in FMR1 mice. High dose MPEP on day 6 of treatment retained anti-convulsant efficacy in mice that had been pretreated for 5 days with low dose MPEP. However, tolerance ensued when low dose MPEP was administered together with low dose R-baclofen over the same 5 day period. Even more surprising was that pre-treatment of the mice with low dose R-baclofen alone for 5 days also induced tolerance to the anti-seizures effects of MPEP given on day 6. Similar to the hypothesis above, if R-baclofen-induced GABA_{B} receptor desensitization leads to increased presynaptic glutamate release, the high dose of MPEP used here might not provide sufficient mGluR5 blockade to prevent seizures.
Another intriguing possibility is that the intracellular signaling pathways of both receptors may converge to promote drug tolerance. Group I mGluRs are coupled to G\(\alpha_q\) and the activation of phospholipase C and release of intracellular Ca\(^{2+}\) via the IP\(_3\) receptor. The GABA\(_B\) receptor is coupled to G\(\alpha_i/G\alpha_o\) G-proteins inducing activation of potassium channels and the inhibition of adenylyl cyclase. Rives et al., 2009 studied cross-talk between these two pathways and reported that stimulation of the GABA\(_B\) receptor strongly potentiates signaling of G\(\alpha_q\) coupled mGluR1, most likely via the activation of phospholipase C from the \(\beta\gamma\) G-proteins subunits generated from complexes with G\(\alpha_i/G\alpha_o\) after GABA\(_B\) receptor stimulation. Interestingly, this effect was only observed when the mGluR and GABA\(_B\) were activated simultaneously, and the mGluR1 potentiation was larger after lower levels of mGluR1 activation compared to higher levels of mGluR1 activation. We propose that the low dose of MPEP used here (Fig. 7), allowed residual signaling through mGluR5 with release of intracellular Ca\(^{2+}\) which was potentiated by R-baclofen stimulation of GABA\(_B\) and accompanied by additional elevation of intracellular Ca\(^{2+}\), thus inducing tolerance to blockade on mGluR5. Although further studies are needed to rigorously test this idea, the results reported here in FMR1 mice, together with those of Rives et al., 2009, suggest that this mechanism could have wider implications and extend to drug combinations that activate or block other classes of G-protein coupled receptors.

Since group I mGluR signaling is enhanced in FMR1 mice we were surprised to find that treatment with a high dose (30 mg/kg) of the mGluR5 positive allosteric modulator CDPPB alone did not exacerbate seizures as predicted, but rather completely prevented audiogenic seizures in FMR1 mice. This anticonvulsant effect appeared to be dose-dependent as 10 mg/kg CDPPB had no effect on seizure activity. Uslaner et al. (2009) reported an inverted U-shaped
dose-response effect whereby improved memory recognition and markers of synaptic plasticity were seen in rats treated with low doses of CDPPB and this effect was lost at the higher dose.

One potential explanation for the observation that CDPPB blocked seizures at high doses in FMR1 mice is that mGluR5 receptor desensitization occurred at the high drug concentration thereby effectively decreasing mGluR5 signaling and reducing audiogenic seizure susceptibility. However, this is unlikely given that tolerance to the anti-seizure effects of high dose CDPPB developed after subchronic administration despite a reduction in mGluR5 expression (Fig. 6). Another possibility is that the pharmacological actions of CDPPB may convert from a positive modulator at low concentrations to a negative allosteric modulator at high concentrations.

CDPPB has been shown to potentiate glutamate stimulation of mGluR5 at very low concentrations with an EC$_{50}$ = 27 nM (Kinney et al., 2005). Moreover, CDPPB binds to the same site as MPEP in the transmembrane region of mGluR5 (Chen et al., 2007; Rodriguez et al., 2010). We obtained support for this idea by examining the effects of CDPPB on mGluR5 expressed in HEK-293 cells. We observed that 10 μM CDPPB blocked glutamate responses in mGluR5 expressing cells, and at 200 nM it reduced the glutamate response (Supplementary Fig. 1). The 200 nM concentration may be pharmacologically relevant as Parmentier-Batteur et al., (2010) has shown that in rats injected with 30 mg/kg CDPPB, brain levels of CDPPB were in the range of 400-800 nM. We speculate that subtle differences in the precise docking orientation within the pocket of some (but perhaps not all) allosteric modulators at this site may have concentration-dependent effects such that positive vs. negative allosteric receptor modulation for some modulators may depend on drug concentration. Together, these findings may have implications for mGluR drug development beyond the treatment of FXS in that
positive allosteric modulators of mGluR5 are being developed for use as novel anti-psychotics (Gasparini et al., 2008; Uslaner et al., 2009; Rodriguez et al., 2010).

There is presently no cure for FXS and current therapies are aimed at treating specific symptoms such as anxiety and hyperactivity. Recent advances in understanding the pathobiology of FXS have led to new and exciting drug targets with the potential to treat the disease itself, rather than individual symptoms (see Levenga et al., 2010 and Hampson et al., 2011 for reviews). Based on these findings, clinical trials are underway examining the use of several mGluR5 negative modulators and the GABA<sub>B</sub> agonist Arbaclofen in treating FXS (www.clinicaltrials.gov). Taken together, the results of our study indicate that in FMR1 mice tolerance develops rapidly to the anti-convulsant effects of R-baclofen, even at very low doses. In addition, cross-tolerance to MPEP occurred after repeated administration of R-baclofen. These results indicate that caution is warranted and that future pre-clinical drug studies should evaluate the effectiveness of long term drug administration.

The monoclonal anti-GABA₉R1 (clone NR3A/49) and GABA₉R2 (clone N81/2) antibodies were obtained from the UC Davis/NIH NeuroMab Facility, supported by NIH grant U24NS050606 and maintained by the Department of Neurobiology, Physiology and Behavior, College of Biological Sciences, University of California, Davis, CA 95616.
Figure legends

Fig. 1. The effects of single and repeated doses of MPEP, R-baclofen, and GS-39783 on audiogenic seizures in FMR1 mice. A, when administered as single doses 60 minutes before testing, MPEP (30 mg/kg) and R-baclofen (1 mg/kg) significantly reduced seizure susceptibility in FMR1 mice. The GABA_B receptor positive allosteric modulator GS-39783 produced a non-significant reduction in seizure incidence. B, FMR1 mice were injected with vehicle, MPEP, R-baclofen or GS-39783 daily for 6 days starting on PND25 and tested for audiogenic seizures 60 minutes after the final injection on PND30. After subchronic treatment, MPEP retained anti-convulsant activity while R-baclofen and GS-39783 did not.

Fig. 2. The effects of low doses of MPEP and R-baclofen on seizures. A, a single dose of 10 mg/kg MPEP or 0.5 mg/kg R-baclofen had no effect on seizure incidence in FMR1 mice. However, when administered in combination, the drugs significantly reduced the incidence of seizures. B, when administered daily for 6 days, 10 mg/kg MPEP or 0.5 mg/kg R-baclofen alone did not block seizures. A combination of 10 mg/kg MPEP plus 0.5 mg/kg R-baclofen also failed to alleviate seizures after subchronic treatment.

Fig. 3. mGluR5 and GABA_B receptor expression after subchronic drug treatment. FMR1 mice were injected with drug daily for 6 days starting on PND25 and the expression of GABA_B R1, R2 and mGluR5 in forebrain was examined by quantitative western blotting after audiogenic seizure testing on PND30. For each condition, 6-8 mice were analyzed. A, FMR1 mice injected with the GABA_B positive allosteric modulator GS-39783 (30 mg/kg) for 6 days showed a significant reduction in GABA_B R1 and R2 expression in the forebrain. C, no differences in GABA_B R1 or R2 expression were observed after subchronic R-baclofen (1 mg/kg) injection. E, mGluR5
protein levels were not altered in mice injected subchronically with MPEP (30 mg/kg) compared to vehicle. B, D, F, representative western blots of GABA<sub>B</sub>R1, R2, and mGluR5 expression after subchronic drug treatment. *p < 0.05, ***p < 0.001.

**Fig. 4.** Expression of GABA<sub>B</sub>R1, R2 and mGluR5 in forebrain of FMR1 mice injected subchronically (daily for 6 days) with a low dose of MPEP (10 mg/kg), R-baclofen (0.5 mg/kg) or combined MPEP + R-baclofen. For each condition, 6-8 mice were analyzed. A, FMR1 mice injected subchronically with low dose MPEP showed a significant decrease in mGluR5 expression compared to vehicle. C, GABA<sub>B</sub>R1 and R2 expression were not significantly altered after subchronic administration of low dose R-baclofen. E, no significant differences in GABA<sub>B</sub>R1, R2 or mGluR5 expression were detected after injection with combined low doses of MPEP plus R-baclofen. B, D, F, representative western blots of mGluR5, GABA<sub>B</sub>R1 and R2 expression after subchronic drug treatment. **p < 0.01

**Fig. 5.** A, the GABA<sub>B</sub> antagonist CGP46381 dramatically increased seizure incidence in FMR1 knockout mice and seizure incidence after treatment with CGP46381 plus MPEP was not different from vehicle indicating that CGP46381 partially blocked the anti-convulsant effect of MPEP. B, treatment with a high dose (30 mg/kg) of the mGluR5 positive allosteric modulator CDPPB completely blocked seizures while a lower dose (10 mg/kg) had no effect on seizure incidence in FMR1 mice. Treatment with 10 mg/kg CDPPB plus 1 mg/kg R-baclofen blocked seizures while treatment with 30 mg/kg CDPPB plus 1 mg/kg R-baclofen produced no significant difference in seizure incidence compared to vehicle; this indicates that a high dose of CDPPB partially blocked the anti-convulsant effects of R-baclofen in FMR1 mice.
**Fig. 6.** The effects of subchronic administration of the mGluR5 positive allosteric modulator CDPPB on seizures and expression of mGluR5. A, subchronic treatment for 6 days (PND25-30) with 30 mg/kg CDPPB did not block audiogenic seizures in FMR1 knockout mice (p > 0.58). B, after subchronic treatment with CDPPB, expression of mGluR5 was decreased (p = 0.056) in FMR1 knockout but not wild-type (p = 0.62) mice. C, representative western blots of mGluR5 expression and the GAPDH loading control in the forebrains of wild-type (top panel) and FMR1 (lower panel) mice.

**Fig. 7.** The anti-convulsant effects of subchronic treatment with low doses of MPEP and/or R-baclofen followed by high dose MPEP. FMR1 knockout mice were treated for 5 days (PND25-29) with low doses of MPEP (10 mg/kg) or R-baclofen (0.5 mg/kg) alone or in combination, and subsequently treated with a high dose of MPEP (30 mg/kg) 60 minutes before seizure testing on PND30. Mice pretreated with 10 mg/kg MPEP displayed no seizures after injection of high dose MPEP. However, pre-treatment with a low dose of R-baclofen alone, or a combination of low dose MPEP plus low dose R-baclofen produced tolerance to the anticonvulsant effects of high dose MPEP.
