Abstract

We compared the differential effects of positional isomers of acetyl salicylic acid (o-ASA, m-ASA, and p-ASA) on COX inhibition, gastric PGE$_2$, MDA, plasma TNF$\alpha$ levels, SOD activity, HT-29 cell growth inhibition, cell proliferation, apoptosis, and cell cycle progression. We also evaluated the gastric toxicity exerted by ASA isomers. All ASA isomers inhibit COX enzymes, but only the o-ASA exerted an irreversible inhibitory profile. We did not observe a significant difference between ASA isomers in their ability to decrease the in vivo synthesis of PGE$_2$ and SOD activity. Furthermore, all isomers increased the levels of gastric MDA and TNF$\alpha$ when administered orally at equimolar doses. We observed a dose-dependent cell growth inhibitory effect, the order of potency was p-ASA > m-ASA = o-ASA. There was a dose-dependent decrease in cell proliferation and an increase in apoptosis, with a concomitant G$_0$/G$_1$ arrest. The ulcerogenic profile of the three ASA isomers showed a significant difference between o-ASA (aspirin) and its two positional isomers when administered orally at equimolar doses (1 mmol/kg); the ulcer index (UI) for o-ASA indicated extensive mucosal injury (UI = 38), whereas m-ASA and p-ASA produced a significantly decreased toxic response (UI = 12 and 8 respectively) under the same experimental conditions. These results suggest that the three positional isomers of ASA exert practically the same biological profile in vitro and in vivo, but showed different safety profiles. The mechanism of gastric ulcer formation exerted by aspirin and its two isomers warrants a more detailed and thorough investigation.
Introduction

2-acetoxybenzoic acid (acetylsalicylic acid or aspirin) is one of the most widely used over-the-counter (OTC) non-steroidal anti-inflammatory drugs (NSAIDs) to treat pain, fever, and inflammation. The major anti-inflammatory and analgesic mechanism of action of aspirin is the inhibition of cyclooxygenase (COX) enzymes (Vane, 1971). COX-1 and COX-2 enzymes catalyze the first step in the enzymatic transformation of arachidonic acid (AA) to prostaglandins (PGs), prostacyclin, and thromboxanes (Txs) (Vane et al., 1998; Smith et al., 2000). COX-1 is generally regarded as a constitutive enzyme that is present in most tissues; it is involved in the physiological production of PGs and provides maintenance functions such as cytoprotection in the stomach. In contrast, COX-2 has been regarded as an inducible enzyme (induced by cytokines, growth factor, interleukin-1-β, carrageenan) and is expressed in inflammatory cells (Masferrer et al., 1994).

Among all NSAIDs, aspirin is a unique non-selective irreversible COX inhibitor because of its ability to acetylate the Ser530 hydroxyl group in the primary active site of COX-1 and COX-2 (Awtry and Loscalzo, 2000). Acetylation of the weakly nucleophilic -OH of Ser530 by aspirin is thought to result from the initial binding of its COOH to Arg120 near the mouth of the COX binding site, which positions the o-acetoxy moiety in close proximity to the Ser530 -OH, which it acetylates. Orally administered aspirin irreversibly acetylates Ser530 of COX-1 and COX-2, leading to complete inhibition of COX-1 activity; nevertheless, the acetylated COX-2 active site remains active converting AA to 15-(R)-hydroxyeicosatetraenoic acid (15-R-HETE), which is the precursor to “aspirin-triggered” endogenous anti-inflammatory lipoxins (Serhan and Chiang, 2002; Yasuda et al., 2008). Consequently, acetylation of COX enzymes by aspirin produces a desirable pharmacological profile, decreasing COX-1–derived PGs and Txs and stimulating the biosynthesis of COX-2–derived endogenous anti-inflammatory lipoxins. These are two of the essential effects that make aspirin an attractive drug in our program tool chest.
Early observations showed that COX-2 is overexpressed in most premalignant and malignant neoplasms, and all essential features of carcinogenesis (mutagenesis, mitogenesis, angiogenesis, reduced apoptosis, metastasis, and immunosuppression) are linked to COX-derived PG biosynthesis (Qiao et al., 1995; Sheng et al., 1998; Kashfi and Rigas, 2005a; Harris, 2007). Thus, it was reasonable to consider that COX-2 was a suitable molecular target for cancer treatment and/or cancer prevention, and NSAIDs may be useful in the treatment of COX-expressing tumors. Based on these hypotheses, NSAIDs (including selective COX-2 inhibitors) have been extensively studied as chemotherapeutic/chemopreventive agents. Evidence suggests that NSAIDs decrease the incidence of, or mortality from, breast cancer, (Holmes et al., 2010; Bardia et al., 2011) colon cancer, (Chan et al., 2007; Cole et al., 2009; Gao et al., 2009; Grau et al., 2009; Cooper et al., 2010) oesophageal cancer, (Liu et al., 2009; Pandeya et al., 2010) non-small cell lung cancer, (Van Dyke et al., 2008) and others. However, there is conflicting evidence showing that the COX inhibitory potency of NSAIDs does not always correlate with their anticancer activity, suggesting that NSAIDs may exert their chemotherapeutic and chemopreventive properties by multiple mechanisms of action other than, or in addition to, COX inhibition (Kashfi and Rigas, 2005a; Kashfi and Rigas, 2005b; Grosch et al., 2006).

Despite the wide variety of desirable pharmacological effects exerted by aspirin, there remains a significant risk of gastrointestinal bleeding, produced (presumably) by the inhibition of cytoprotective COX-mediated gastric PG synthesis, even with low prophylactic doses of this drug. (Yeomans et al., 2009) This mechanism-based toxicity is the main reason why the use of aspirin (and NSAIDs in general) has been correlated with a relatively high incidence of adverse gastrointestinal side effects, (Singh and Triadafilopoulos, 1999; Tenenbaum, 1999; Aalykke and Lauritsen, 2001; Fiorucci and Del Soldato, 2003; Schaffer et al., 2006) and has led some clinicians (and patients) to reduce their use (Scheiman and Fendrick, 2007).
In the last fifteen years, several research groups have reported extensive structure-activity relationships (SAR) on a wide variety of COX pharmacophores. In this regard, the attention was essentially focused on developing potent and selective COX-2 inhibitors based on the assumption that COX-2–derived PGs were uniquely and directly responsible for the inflammatory processes, and COX-1–derived PGs were mainly involved in cytoprotection; however, recent reports have challenged these “traditional” roles for COX-1 and COX-2 enzymes, emphasizing the importance of re-evaluating their roles in the inflammatory process, (Rouzer and Marnett, 2009) as well as their contribution in the underlying mechanisms of NSAID-induced side-effects.

Considering the simplicity of aspirin’s chemical structure, it is surprising that there are no reports in the literature describing the SARs for the other two positional isomers of aspirin, namely the meta- and para-acetylsalicylic acid isomers. Therefore, as part of an ongoing research work aimed to develop new anticancer agents derived from aspirin, we now report a comprehensive biological evaluation of acetylsalicylic acid positional isomers, comparing their anti-inflammatory profile, their differential effects on cancer cell (HT-29) growth inhibition, cell proliferation, cell cycle, and apoptosis. We also evaluated the gastric ulcerogenic profile of aspirin’s positional isomers, as well as a comprehensive molecular modeling (docking) study for the three isomers (o-, m-, and p-) of acetylsalicylic acid (ASA) on COX-2.
Methods

Reagents. The three positional isomers of salicylic acid (o-SA, m-SA, p-SA), acetyl salicylic acid (o-ASA) and 4-(acetyloxy)-benzoic acid (p-ASA) were purchased from MP biomedicals (Solon, OH). 3-(acetyloxy)benzoic acid (m-ASA) was prepared by acetylation of m-salicylic acid, Fig 1. HPLC grade solvents and reagents acquired from Fisher chemicals were used; the colon adenocarcinoma HT-29 cell line (ATCC HTB-38, Manassas, VA), McCoy’s 5A medium, and ovine COX-1 and COX-2 were obtained from Cayman chemicals (Ann Arbor, MI).

Animals. All experimental procedures were approved by the institutional animal research committee at the City College of New York, and performed in accordance with nationally approved guidelines for the treatment of laboratory animals. Male wistar rats (five per group, obtained from Charles River Laboratories Inc., Wilmington, MA) weighing 180-200 g were used. The rats were fed with standard laboratory chow and water; however, before each experiment, the rats were fasted for 48 h but allowed to have free access to drinking water at all times. The experimental drugs were administered orally (gavage) by forming suspensions of o-ASA, m-ASA, or p-ASA (1 mmol/kg) in 1.0 mL of 1% carboxymethyl cellulose solution. The same volume of carboxymethyl cellulose solution was administered to the animals in the control group. Six hours after administration, the rats were euthanized by suffocation in a CO2 chamber, and had their stomachs removed, cut along the greatest curvature, and rinsed with ice-cold distilled water. The ulcer index (UI) was determined for each experimental drug based on a previously reported procedure by Best et al. (Best et al., 1984). Additionally, tissues from the rat stomachs were excised and processed to measure the levels of PGE2 and malondialdehyde (MDA), as well as the activity of superoxide dismutase (SOD) enzyme. To determine plasma levels of TNF-α, blood samples from each rat were taken by cardiac puncture using heparin-containing vials.
**Determination of PGE₂ levels.** Around 1 g of stomach tissue from each rat was removed and weighed and placed into a test tube containing 5 mL of pH 7.4 phosphate buffer (0.1 M), EDTA (1 mM), and indomethacin (10 µM). Each tissue sample was homogenized and centrifuged for 10 min at 12,000 rpm (4°C), and then the amount of PGE₂ in supernatants (duplicate) was determined by an enzyme immunoassay kit (Cayman Chemical Inc., Ann Arbor MI) following the protocol described by the manufacturer. Briefly, the standard (50 µL) or homogenate (50 µL), enzymatic tracer (50 µL), and specific antiserum (50 µL) was mixed; after incubation for 17 h (overnight) at 4°C, the plates were washed with wash buffer, and Ellman’s reagent (200 µL) was added into each well. The absorbance at 412 nm was measured after incubating the plate for 1 h at room temperature. The amount of detected prostaglandin was expressed as picograms of PGE₂ per milligram of protein; the protein levels were determined in a separate assay (Bio-Rad Laboratories, Hercules, CA).

**Index of lipid peroxidation.** Approximately 25 mg of stomach tissue from each rat was snap frozen and sonicated for about 15 s at 40 V, over ice, using 250 µL of radioimmunoprecipitation assay buffer (25 mM Tris-HCl, pH 7.6, 150 mM NaCl, 1% Tergitol-type NP-40 nonylphenoxypolyethoxyethanol, 1% sodium deoxycholate, and 0.1% SDS) and phenylmethylsulfonyl fluoride as protease inhibitor; then, cell homogenates were centrifuged for 10 min at 1600 rpm (4°C). The amount of thiobarbituric acid-reactant substances in the supernatants were measured and stored on ice by a colorimetric kit (Cayman Chemical Inc., Ann Arbor MI) following the protocol described by the manufacturer. Briefly, the reaction of MDA with thiobarbituric acid at high temperature (90–100°C) in acidic conditions produced a chromophore which absorbed visible light at 530-540 nm. The results were expressed as picomoles of malondialdehyde per gram of protein (as determined by a Bio-Rad assay).
Superoxide dismutase activity. The activity of antioxidant enzymes (SOD) was determined in samples of gastric mucosal tissue isolated from each rat by a colorimetric assay kit (Cayman Chemical Inc., Ann Arbor MI) according to the protocol described by the manufacturer. Briefly, around 1 g of mucosal tissue was homogenized with 5 mL of 20 mM HEPES buffer (pH 7.2) containing EGTA (1 mM) and sucrose (300 mM). Then, cell homogenates were centrifuged at 1500 rpm for 10 min (4°C). The supernatants were removed and stored at −80°C until assayed. SOD activity was determined using a spectrophotometric method measuring absorbance at 460 nm; the results were expressed as units of SOD activity per milligram of protein. In this regard, one unit of SOD is defined as the amount of enzyme required to exhibit 50% dismutation of the superoxide radical.

Plasma TNF-α levels. Fresh samples of blood from animals were collected by cardiac puncture, receiving the fluid into heparin-containing vials. TNF-α plasma levels were determined using an enzyme immunoassay kit (R&D Systems, Minneapolis, MN) according to the protocol described by the manufacturer; the results were expressed as picograms of TNF-α/mL. Briefly, each sample (50 μL) was incubated with antibodies specific for rat TNF-α, and then the samples were washed three times with assay buffer. An enzyme-linked polyclonal antibody specific for rat TNF-α (conjugated to horseradish peroxidise) was added to the wells. After washing unbound antibody-enzyme complexes, a substrate solution containing tetramethylbenzidine (TMB) and hydrogen peroxide were added to the wells. This enzymatic reaction yielded a blue product (oxidized TMB) that turned yellow when we added dilute hydrochloride acid. The intensity of the color by spectrophotometry was determined measuring optical densities (OD) at 450 nm in a standard enzyme-linked immunosorbent assay plate reader. The sensitivity of this assay was determined (around 1.6 pg/mL) by adding 2 standard deviations to the mean OD value of 20X.
zero standard replicates, and calculating the corresponding concentration. The results are expressed as picograms per milliliter.

**Cell growth inhibition.** HT-29 human colon adenocarcinoma cells were cultured in McCoy’s 5A medium as per ATCC instructions; the cell growth inhibitory effect of o-ASA, m-ASA and p-ASA (100 mM in DMSO) was measured using a colorimetric MTT assay kit (Roche, Indianapolis, IN) (Kashfi et al., 2002). To avoid interference from the solvent, the final concentrations of DMSO were adjusted to 1% in all media.

**Assay for apoptosis and cell proliferation.** HT-29 cells (approximately $0.5 \times 10^6$ cells/mL) were incubated with various concentrations of o-ASA, m-ASA and p-ASA for 24 h. The treated cells were washed and resuspended with 1X Binding Buffer (Annexin V binding buffer, 0.1 M HEPES/NaOH, pH 7.4, 1.4 M NaCl, 25 mM CaCl₂; BD BioSciences Pharmingen, San Diego, CA). Then, 5 mL of Annexin V-FITC (final concentration: 0.5 mg/mL) was added followed by propidium iodide (final concentration 20 mg/mL). Finally, the cells were incubated at room temperature for 15 min in the dark, transferring them to FACS tubes for subsequent analysis. The percentage of apoptotic cells was calculated using a Becton Dickinson LSR II, equipped with a single argon ion laser. For each subset, about 10,000 events were analyzed. All the parameters were collected in list mode files, and the data was analyzed using the Flow Jo software.

The levels of proliferating cell nuclear antigen (PCNA) was determined using an ELISA Kit (Calbiochem, La Jolla, CA), in accordance with the manufacturers protocol. Briefly, HT-29 cells were incubated with serum-free media for 24 hours to remove the effect of endogenous growth factors. Then, the cells ($1 \times 10^6$ cells/mL) were treated with various concentrations (1-5 mM) of o-ASA, m-ASA and p-ASA. After this, the cells (approximately $1 \times 10^6$ cells/mL) were suspended in suspension buffer (5 mM EDTA, 0.2 mM PMSF, 1 μg/mL pepstatin, 0.5 μg/mL
leupeptin, and 50 mM Tris-HCl, pH 8.0). The samples of the suspension were pipetted into the wells of the plate containing rabbit polyclonal antibody (specific for the human PCNA protein) included with the kit. Then, mouse monoclonal antibody clone PC10 (detector antibody) was added to each well, and the mixture was incubated for 2h at room temperature. After washing the wells, horseradish peroxidase streptavidin solution was added, and the plate was incubated for 30 min at room temperature; the chromogenic substrate tetramethylbenzidine was added and the plates were incubated again for a further 30 min. Finally, the stop solution was added and the absorbance was measured in each well at 450 nm.

**Cell cycle analysis.** Cell cycle phase distributions of control were obtained and HT-29 cells were treated by using a Coulter Profile XL equipped with a single argon ion laser. For each subset, >10,000 events were analyzed. All the parameters were collected in list mode files. The data was analyzed on a Coulter XL Elite Work station using the software programs Multigraph™ and Multicycle™. Cells (approximately 0.5 x 10^6) were fixed in 100% methanol for 10 min at -20°C, pelleted (5000 rpm x 10 min at 4°C), resuspended, and incubated in PBS containing 1% FBS/0.5% NP-40 on ice for 5 min. After that, the cells were washed again with PBS/1% FBS containing 40 mg/mL propidium iodide (used to stain DNA), and 200 mg/mL RNase type IIA. The analysis was carried out within the next 30 min by flow cytometry. The percentage of cells in G0/G1, G2/M, and S phases were determined from DNA content histograms.

**Cyclooxygenase inhibition assay.** Ovine COX-1 or COX-2 (200 units) were incubated in the presence of o-ASA, m-ASA, or p-ASA (1-5 mM in DMSO) in 600 µL of reaction buffer (100 mM Tris-maleate buffer, pH 6.5, 0.1% Tween-20, gelatin at (1 mg/mL), hematin (3 μM), and TMPD (100 µM, Sigma-Aldrich, St. Louis, MO). The concentration of DMSO was always 10% of the final volume. After incubating the samples for 30 min at 4°C, arachidonic acid (100 µM) was added to start the enzymatic reaction, this was incubated for 5 min at 25°C. The COX enzymes
activity was measured by monitoring the oxidation of TMPD at 600 nm in a microtiter plate. The percent inhibition was determined as follows: \( [(IA-D)/IA] \times 100 \); where \( IA \) = average absorbance from the 100% initial activity wells, and \( D \) = average absorbance from the corresponding drug wells. Additionally, the reversibility of COX inactivation exerted by acetylsalicylic acid isomers were assessed by carrying out a microdialysis procedure. In this regard, COX-1 or COX-2 (2000 units) was incubated in the presence of \( \sigma \)-ASA, \( m \)-ASA, or \( p \)-ASA (1-5 mM in DMSO) in 1000 \( \mu \)L of reaction buffer for 30 min at 4°C. After incubation, the samples were loaded into microdialysis chambers (10-kDa molecular mass cut-off membrane, Amicon Inc.) and dialyzed against 500 \( \mu \)L of inhibitor-free reaction buffer for 2 hr. After dialysis, the remaining enzymatic activity was determined as described above (without adding more inhibitor).

**Ulcerogenicity.** Two different experiments were conducted to compare the gastric toxicity exerted by the three aspirin isomers, namely the ulcer index (UI) and the erosion index (EI) assays. The ulcer index (UI) was determined as described by Best et al (Best et al., 1984). \( \sigma \)-ASA, \( m \)-ASA, or \( p \)-ASA (1 mmol/kg) were administered by gavage, suspended in 1% carboxymethyl cellulose solution (1.0 mL). Animals in the control group received an equivalent volume of vehicle. UI measured clearly visible ulcers (elongated, hemorrhagic lesions varying in length); whereas EI measured less noticeable micro-hemorrhagic lesions, which were only observed using a magnifying lens.

**Docking protocol.** A series of molecular modeling (docking) experiments were performed using Discovery Studio Client v2.5.0.9164 (2005-09, Accelrys Software Inc.), running on a HP xw4600 workstation (Processor x86 family 6 model 23 stepping 10 Genuine Intel 2999 MHz). The coordinates were obtained for the X-ray crystal structure of the enzyme COX-1 and COX-2 from the RCSB Protein Data Bank; hydrogens ions were added after download. The ligand molecules
were constructed using the Build Fragment tool and minimizing the energy for 1000 iterations until reaching a convergence equal to, or lower than 0.01 kcal/mol Å. The docking experiment on COX-1 (PDB file 1prh) was carried out by suitably positioning the energy minimized ligand in the active site while carefully monitoring non-bonded interactions of the ligand-enzyme assembly and any side chain bumps; in contrast, the docking experiment on COX-2 was carried out by superimposing the energy minimized ligand on SC-558 in the PDB file 1cx2, at which point we deleted the structure of SC-558. In all experiments, the resulting ligand-enzyme complex was docked using the Libdock command (protocol of Discovery Studio) after defining subsets of the enzyme within a 10 Å radial distance from the ligand. In this regard, the force field Chemistry HARvard Macromolecular Mechanics (CHARMM) was employed for all docking experiments. Subsequently, a molecular dynamics (MD) simulation was conducted with the corresponding ligand–enzyme complex using a simulation protocol at a temperature of 300 K, a 100 step equilibration/1000 iterations, a time step equal to 1 fs, and a distance-dependent dielectric constant $4r$. Finally, (by 1000 iterations) the optimal binding orientation of each ligand–enzyme complex was minimized by using the conjugate gradient method until reaching a convergence = 0.001 kcal/mol Å. The different intermolecular energies ($E_{\text{intermolecular}}$) between the ligand and the enzyme were evaluated and compared and, expressed in kcal/mol.

**Statistics.** All data are presented as the mean ± SEM, with sample sizes of at least 5 rats/group (unless otherwise specified). Comparisons between groups were performed using a one-way analysis of variance followed by the Student-$t$ test.
**Results**

**Determination of PGE₂ Levels.** We observed that all three isomers of acetylsalicylic acid (1 mmol/kg) decreased the COX-mediated prostaglandin E₂ synthesis from 73 ± 4.4 pg/mg protein in the control group, to about 10 pg/mg protein in animals treated with o-ASA, m-ASA, or p-ASA. This represents about 86% reduction in PGE₂ levels in gastric tissue compared to the control group; however, we did not find a statistically significant difference between the three ASA isomers, since m-ASA (9.7 ± 1.0 pg/mg protein) and p-ASA (10.7 ± 1.5 pg/mg protein) decreased the biosynthesis of PGE₂ to the same extent as compared to o-ASA (11.8 ± 1.2 pg/mg protein). These results are shown in Figure 2A.

**Index of Lipid Peroxidation.** We determined the in vitro modulatory effects of o-ASA, m-ASA, and p-ASA (1 mmol/kg) on the peripheral markers of oxidative stress and lipid peroxidation, namely malondialdehyde (MDA). As shown in Figure 2B, the three positional isomers of aspirin increased the gastric tissue concentration of MDA. In this regard, we observed a significant increase in MDA levels from 8.4 ± 3.0 nmol/mg in the control group, to 59.4 ± 2.1 nmol/mg for o-ASA, 63.0 ± 2.0 nmol/mg for m-ASA, and 66.6 ± 2.6 nmol/mg protein for p-ASA. This represents about a 7-fold increase in gastric MDA compared to the control group. According to these results, there appears to be a direct relationship between the chemical structure of ASA isomers and MDA levels. As we increased the distance between the acetoxy group and the carboxylic acid moiety present in aspirin (o-acetylsalicylic acid), the concentration of MDA also increased (p-ASA > m-ASA = o-ASA); however, this change was not statistically significant among ASA isomers and a definite conclusion in this regard cannot be made.

**Superoxide Dismutase Activity.** We also determined the in vitro modulatory effects of o-ASA, m-ASA, and p-ASA (1 mmol/kg) on the activity of the antioxidant enzyme superoxide dismutase (SOD). As shown in Figure 2C, the three positional isomers of aspirin decreased the catalytic
activity of SOD expressed in samples of gastric tissue. We observed a significant decrease in SOD activity from \(2.9 \pm 0.3\) U/mg protein in the control group, to \(1.1 \pm 0.4\) U/mg for \(\alpha\)-ASA, \(1.0 \pm 0.2\) U/mg for \(m\)-ASA, and \(0.8 \pm 0.3\) U/mg for \(p\)-ASA. Although there appears to be a downward trend in SOD enzymatic activity as a function of positional isomerism, a relationship between these two entities cannot be established.

**Plasma TNF-\(\alpha\) Levels.** The oral administration of \(\alpha\)-ASA, \(m\)-ASA, or \(p\)-ASA (1 mmol/kg) produced a significant increase in the expression of the pro-inflammatory mediator TNF-\(\alpha\), compared to that obtained in samples of gastric mucosa from control rats. In this regard, we determined the basal levels of TNF-\(\alpha\) in animals receiving vehicle (control group) to be \(5.2 \pm 1.3\) pg/mL, whereas the levels of this protein in treatment groups increased to \(194.9 \pm 3.1\) pg/mL (\(\alpha\)-ASA), \(181.5 \pm 4.3\) pg/mL (\(m\)-ASA), and \(187.7 \pm 2.9\) pg/mL (\(p\)-ASA). Based on these results, all three positional isomers of ASA were equally potent in increasing plasma TNF-\(\alpha\) levels, Figure 2D.

**Cancer Cell Growth Inhibition.** When we incubated the human colon adenocarcinoma HT-29 cells (0.5 × 10^6 cells/well) with \(\alpha\)-ASA, \(m\)-ASA, or \(p\)-ASA, we observed a concentration-dependent cell growth inhibitory effect. All drugs were incubated at the same concentrations (0, 1, 2, 3, and 5 mM) during a 24 h incubation period. Under these conditions, we observed that all ASA isomers exerted a modest inhibition in cell growth (28-43%) compared to control cells treated with vehicle (DMSO) only. According to our results, there was a direct and statistically significant relationship between the chemical structure of ASA isomers and cell growth inhibition. As we increased the distance between the acetoxy group and the carboxylic acid moiety present in aspirin (\(\alpha\)-acetylsalicylic acid), there was a small but significant increase in cancer cell growth inhibition (\(p\)-ASA > \(m\)-ASA = \(\alpha\)-ASA). The most potent isomer was \(p\)-ASA, which decreased cell growth by about 43% compared to vehicle-treated cells; at the highest test
compound concentration used in this experiment (5 mM). These results are graphically represented in Figure 3.

**Assay for apoptosis.** Resistance against apoptosis is critical for cancer cell survival; therefore, we determined the percent of cells undergoing apoptosis upon incubation with \(\alpha\)-ASA, \(m\)-ASA, and \(p\)-ASA at different concentrations (3 and 5 mM) by the Annexin V assay. According to our results, we observed a dose-dependent induction of apoptosis in HT-29 cells exerted by all ASA isomers; the percent of cells undergoing apoptosis increased from 0 in control cells to about 15 % in cells treated with ASA isomers at 3 mM, whereas the percentage of apoptotic cells was significantly higher (about 40 %) in cells incubated in the presence of 5 mM \(\alpha\)-ASA, \(m\)-ASA, or \(p\)-ASA. The distance between the acetoxy group and the carboxylic acid moiety present in acetylsalicylic acid isomers was not a determinant for inducing apoptosis (see Figure 4A).

**Cell Proliferation.** To elucidate the mechanism underlying the effect of ASA isomers on cancer cell growth, we also determined the modulatory effect exerted by \(\alpha\)-ASA, \(m\)-ASA, and \(p\)-ASA on cell proliferation. In this regard, we measured the expression of proliferating cell nuclear antigen (PCNA) in human adenocarcinoma HT-29 cells incubated for 24 h in the presence of ASA isomers (1, 3, and 5 mM). We observed that all ASA isomers exerted a dose-dependent decrease in cancer cell proliferation by reducing PCNA expression in HT-29 cells from 100 % in the control group, to 57-87% in treated cells (see Figure 4B). At 1 mM, the three ASA isomers exerted a non-significant reduction in PCNA expression; however, this decrease was significant in cells treated with 3 mM or 5 mM \(\alpha\)-ASA, \(m\)-ASA, or \(p\)-ASA. The modulation of cell proliferation induced by ASA isomers was not conclusively correlated with structural differences in these molecules; it was only at the highest test compound concentration (5 mM) that we observed a modest non-significant correlation (\(\alpha\)-ASA > \(m\)-ASA > \(p\)-ASA) between them.
Cell Cycle Analysis. We incubated human adenocarcinoma colon cancer (HT-29) cells in the presence of the three positional isomers of ASA for 24 h, analyzing the end results by flow cytometry. We observed that o-ASA, m-ASA, and p-ASA induced a similar dose-dependent accumulation of HT-29 cells in the G₀/G₁ phase, relative to the population of cells in G₀/G₁ phase in the untreated control (40.3 ± 0.9 %). For example, treatment of HT-29 cells with o-ASA increased the relative population of HT-29 cells in G₀/G₁ phase from 0 to 69.3 ± 0.6 % at 3 mM, and 86.3 ± 0.8 % at 5 mM. The phase-specific cell cycle arrest exerted by the m-ASA (66.7 ± 0.6 % at 3 mM, 82.7 ± 0.8% at 5mM), and p-ASA (62.4 ± 0.6 % and 87.2 ± 0.8 % at 3 and 5 mM respectively). These results are represented graphically in Figures 5A-C.

Cyclooxygenase Inhibition assay. We determined the percent of enzyme inhibition exerted by o-ASA, m-ASA, and p-ASA isomers following two different protocols. In the first protocol, we carried out a concentration-dependent (1, 3, 5 mM) COX inhibition (Table 1), whereas in the second protocol, we measured the percent of COX-1 inhibition exerted by m-ASA at different time points (2, 5, 15, 30, and 120 min) at 1mM (Table 2). To estimate the extent of irreversible acetylation exerted by the different ASA isomers, we determined the percent of COX inhibition after filtration of the corresponding inhibitor solution by microdialysis.

Results obtained in the first protocol showed a concentration-dependent COX inhibition exerted by o-ASA, m-ASA, and p-ASA. In this regard, we observed that aspirin (o-ASA) exerted a marked inhibitory profile on COX-1 by inhibiting the catalytic activity of this enzyme (72-93% inhibition) within the range of concentrations used (1-5 mM), and this profile did not change after replacing the medium by microdialysis (Table 1). However, the inhibitory profile exerted by the other two ASA isomers was significantly lower at 1 mM (o-ASA = 54%, m-ASA = 48%) and 3 mM (o-ASA = 63%, m-ASA = 71%). In contrast, we observed that at 5 mM, the three ASA isomers exerted the same inhibitory profile (93 ± 4, 88 ± 2, and 94 ± 3 % inhibition for o-ASA, m-ASA, and p-ASA respectively). Nevertheless, unlike the o-ASA isomer, the m-ASA and p-ASA
compounds exerted a significantly lower COX-1 inhibitory profile after microdialysis (see Table 1).

In regards to COX-2 inhibition, we observed that before microdialysis, the three ASA isomers exerted the same degree of enzyme inhibition. For example, the o-ASA isomer inhibited COX-2 by 83 ± 2 and 95 ± 2% at 3 and 5 mM respectively, whereas the m-ASA and p-ASA isomers inhibited this enzyme by 80 ± 2%, 80 ± 3% at 3 mM, and 99 ± 3, 94 ± 4 at 5 mM. However, as it was noted for COX-1 inhibition, only the o-ASA isomer exerted the same degree of COX-2 inhibition before and after microdialysis, since the other two isomers exerted a significantly lower inhibitory profile after microdialysis. For example, the m-ASA isomer inhibited COX-2 by 56 ± 3 at 3 mM after the microdialysis protocol, compared to 80 ± 2% before microdialysis at the same concentration. The same trend was observed for this compound at 5 mM (99 ± 3 and 76 ± 4% inhibition before and after dialysis respectively).

The second protocol showed that m-ASA decreased the enzymatic activity of COX-1 in a time-dependent manner. However, this time-dependent inhibition was observed only within the first 30 min, because at the last time-point (120 min) we observed an 11% decrease in potency (43% inhibition compared to 54% at 30 min). As it was noted for the concentration-dependent experiments described above, in the time-dependent protocol we also observed a significant decrease in potency after removal of the inhibitor by microdialysis (Table 2).

Ulcerogenicity. We carried out two different assays to evaluate the toxic side-effects exerted by an acute oral equimolar (1 mmol/kg) dose of o-ASA, m-ASA, and p-ASA isomers. In the first experiment, we determined macroscopic ulcerative lesions in the glandular region of the rat stomach (“ulcer index”; Figure 6A), in the second one we determined smaller points (erosions) on the stomach epithelial layer (“erosion index”; Figure 6B), which are only visible using a magnifying lense. In this regard, animals in the control group showed a normal glandular region with no ulcers or erosions on the luminal surface (UI = EI = 0). As expected, the administration
of o-ASA resulted in extensive mucosal injury (UI = 45 ± 3.1) to the glandular portion of the gastric fundus; however, the administration of m-ASA (UI = 14 ± 3.0) and p-ASA (UI = 17 ± 4.1) produced a significantly decreased ulcerogenicity compared to the o-isomer. On the other hand, when we compared these drugs in the erosion index assay, we observed an opposite trend where aspirin (EI = 28 ± 1.7) was the least toxic compound. The positional isomers of aspirin m-ASA (EI = 46 ± 4.0) and p-ASA (EI = 41 ± 4.1) were significantly more aggressive in this assay compared to the o-ASA isomer.

**Docking results.** We carried out a comprehensive molecular modeling (docking) study to evaluate the differential binding interactions observed between o-ASA, m-ASA, and p-ASA isomers within the active sites of COX-1 and COX-2. These results are summarized below.

**Docking aspirin in COX-1.** The most stable enzyme-ligand complex (Figure 7A) showed that the central phenyl ring was oriented in a hydrophobic region at the centre of the COX active site, surrounded by Leu352, Leu384, Tyr385, Trp387, Ile523, and Met522 (distance < 5 Å). The C-1 carboxylate of aspirin was oriented toward the mouth of the active site closer to polar amino acids such as Arg120 and Tyr355. The carboxylate (COOH) underwent two electrostatic interactions with both hydrogen atoms of NH₂ of Arg120 (distance < 4 Å), and was about 4.9 Å away from OH of Tyr355. As expected, the C-2 acetox substituent (OOCCH₃) was oriented 4.20 Å away from OH of Ser530 (reported acetylation site for aspirin) in the COX-1 active site. Moreover, the acetox CH₃ group underwent nonpolar binding interactions (< 5 Å) with Val349 and Leu531. This indicates that the C-2 acetox group in aspirin is suitably positioned to irreversibly acetylate Ser530.

**Docking aspirin in COX-2.** The most stable enzyme-ligand complex (Figure 7D) showed that the central phenyl ring of aspirin was oriented in a region at the centre of the active site surrounded by Val349, Leu352, Leu384, Trp387, Met522, Val523, and Ala527 (distance < 5 Å). The C-1 carboxylate was oriented close to the mouth of the COX-2 active site, and the
carboxylate COOH was about 6.4 Å away from NH2 of Arg120, and about 5.3 Å away from OH of Tyr355. The C-2 acetoxy (OCOCH3) substituent was oriented toward Tyr385 and Ser530; the carbonyl (C=O) was about 3.4 Å away from OH of Ser530. The C=O group also formed a hydrogen bond with OH of Tyr385 (distance = 3.07 Å), which plays a role in the aspirin-mediated acetylation of Ser530.

**Docking ASA isomers in COX-1.** The most stable enzyme-ligand complexes (Figures 7B and 7C) showed that the central phenyl rings were oriented in a hydrophobic region at the centre of the active site surrounded by Leu352, Phe518, Ile523, Met522, and Ala527 (distance < 5 Å). The C-1 carboxylate of both m-ASA and p-ASA was oriented toward the mouth of the active site closer to the polar amino acids Arg120 and Tyr355. As noted for aspirin, the carboxylate (COOH) moieties in m-ASA and p-ASA were about 3.6 and 3.5 Å away from OH of Tyr355 respectively, undergoing electrostatic interactions with both hydrogen atoms of NH2 of Arg120 (distance < 2.5 Å). The C-3 acetoxy group (OCOCH3) was oriented toward the apex of the COX-1 active site (Leu352, Typ385, and Trp387), which locates their C=O ester group near (about 4.3-5.5 Å away) from OH of Ser530. This suggests that, despite the *meta* and *para* relationships between the carboxy and the ester groups in these ASA isomers, the acetoxy moiety is still located near polar amino acids at the active site and favors the orientation of the acetoxy groups toward Ser530, the acetylation site for aspirin.

**Docking ASA isomers in COX-2.** We observed that the central phenyl rings were also oriented in a hydrophobic region at the centre of the COX-2 active site surrounded by Val349, Leu352, Ser353, and Val523 (around 5 Å away). The C-1 carboxylate of the two aspirin derivatives was oriented close to the mouth of the COX-2 active site; the carboxylate COOH moieties formed a hydrogen bond with OH of Tyr355 (distance = 3.2 and 3.4 Å for m- and p-ASA respectively), and were about 4.1-5.8 Å away from Arg120. Due to the presence of a small Val523 in the COX-2 active site, we observed that the phenyl ring with the C-1 acid substituent in m-ASA was able to interact with polar amino acid residues (His90 and Arg513) present in the secondary
pocket of COX-2; this was not the case for p-ASA. These observations indicate that the COOH group in m-ASA acted as an anchor orienting the acetoxy group toward Ser530, the acetylation site of aspirin. However, for both isomers, the C-3 acetoxy substituent (OCOCH₃) was oriented toward the apex of the active site in a hydrophobic region comprised of Leu384, Tyr385, Trp387, Phe518, and Met522 (distance < 5 Å), and the distances between the acetoxy group (OCOCH₃) in m-ASA and p-ASA and the OH of Ser530 (the acetylation site of aspirin), were about 6.75 and 5.6 Å respectively (see Figures 7E and F).
Discussion

The major pharmacological mechanism of action exerted by NSAIDs is the inhibition of COX-1 and COX-2 enzymes. Aspirin is the only NSAID that irreversibly inhibits both enzymes, decreasing the amount of pro-inflammatory prostaglandins; consequently, aspirin also decreases the production of cytoprotective PGE2 in vivo (Ligumsky et al., 1982; Lichtenberger et al., 2007). When administered at equimolar doses (1 mmol/kg p.o.), o-ASA, m-ASA, and p-ASA exerted the same biological profile, which suggests that all acetylsalicylic acid isomers inhibited, to the same extent, COX-derived PGE2 synthesis in gastric tissue. In the present study, we did not evaluate the anti-inflammatory profile of ASA isomers, but according to these results, it is reasonable to assume that regardless of positional isomerism, the acetylsalicylic acid COX pharmacophore is equally effective in decreasing the biosynthesis of PGs locally and systemically.

The enzymatic inhibition of COX enzymes exerted by aspirin (IC50 values) reported in the literature varies considerably, depending on the experimental conditions used for the particular assay. In the present study, we have worked with an in vitro system with purified ovine COX-1 and COX-2 resuspended in a reaction buffer with no cell fractions, thus excluding enzymatic degradation of ASA isomers by non-specific esterases. The irreversible inhibition of COX enzymes exerted by o-ASA is demonstrated by comparing the activity of COX-1 and COX-2 before and after microdialysis, which after 30 min of incubation eliminates any unbound drug from the enzyme suspension by filtration through a semi-permeable membrane. We observed that only the o-ASA isomer showed the same degree of inhibition before and after microdialysis, whereas the m-ASA and p-ASA isomers showed lower inhibitory profiles after the drug was removed. This may suggest that either the m-ASA and p-ASA exert a lower degree of acetylation in the active site compared to o-ASA, or they reversibly inhibit COX-1 and COX-2 enzymes. In this regard, we used indomethacin as reference drug. After dialysis, the potency of
indomethacin decreased considerably from 69% to 24% on COX-1, and from 67% to 32% inhibition on COX-2, which clearly showed a reversible pattern of enzyme inhibition.

To investigate the potential irreversible inhibition of COX enzymes exerted by the three ASA isomers, we carried out a series of molecular modeling (docking) studies to evaluate their differential binding interactions within the active site of COX enzymes. As expected, the acetyl group in \( \alpha \)-aspirin was oriented toward the Ser530 residue in both proteins; however, we observed that despite a few differences in orientation between \( m \)- and \( p \)-ASA isomers, these compounds also adopt relatively favorable conformations which may lead to acetylation of Ser530. This observation is supported by the bioequivalent in vivo profile (decrease in PGE\(_2\) levels) exerted by all ASA isomers when administered orally to rats.

The significant increase in the levels of MDA in samples of gastric tissue, suggests that \( \alpha \)-ASA, \( m \)-ASA, and \( p \)-ASA induced oxidative stress to the same extent. According to our results, changes in the relative position of the carboxylic acid group relative to the acetoxy group did not alter the well established tendency of aspirin (Chattopadhyay et al., 2010) to induce an intracellular oxidative environment. This observation correlates well with the observed decrease in the activity of SOD in gastric tissue. In a previous study, our group reported the inhibitory activity of aspirin on this antioxidant enzyme; (Chattopadhyay et al., 2010) according to the results obtained in the present work, the other two ASA isomers are equally suited to decrease the catalytic activity of SOD. Furthermore, we observed that all ASA isomers exerted an up-regulation of the pro-inflammatory mediator TNF\(_\alpha\), which has been reported to trigger the adherence and activation of leukocytes, leading to the release of oxygen-derived free radicals (oxygen superoxide) and proteases, producing epithelial injury (Perini et al., 2004). However, despite these observations suggesting that all ASA isomers would exert the same degree of gastric toxicity, we were surprised to see that, according to the ulcer index assay, the \( \alpha \)-ASA was significantly more ulcerogenic than the \( m \)-ASA or \( p \)-ASA isomers. This piece of information...
is interesting, considering that all isomers decreased PGE$_2$ levels, increased cellular oxidative stress as determined by MDA, and inhibited the antioxidant enzyme SOD to the same extent. If we analyze the results obtained in the ulcer index assay, we could speculate that the position of the acetyl group (COCH$_3$) relative to that of the carboxylic acid (COOH) moiety in acetylsalicylic acids, plays a major role in the ulcerogenic response. However, when we compared the erosion index for all ASA isomers, we observed that the m-ASA and p-ASA isomers are significantly more toxic than o-ASA, producing more epithelial gastric erosions at equimolar doses. This structure-activity relationship may be useful in future studies to fine tune the pharmacological and toxicological profile of ASA derivatives, and warrants further studies.

The use of NSAIDs has been correlated with a lower incidence of colon cancer among regular users of these drugs (Chan et al., 2007; Cole et al., 2009; Gao et al., 2009; Grau et al., 2009; Cooper et al., 2010). We know that NSAIDs induce apoptosis in many cells and in response to different stimuli. Proposed mechanisms for the pro-apoptotic effects include activation of caspases, induction of cytochrome c release, regulation of protein kinase C, inhibition of NF-κB, and suppression of AP-1 (Wong et al., 2004). In the current study, we determined that there was a significant difference between ASA isomers in their ability to inhibit cancer (HT-29) cell growth in vitro, where p-ASA was the most potent isomer, followed by the m-ASA and the o-ASA. This biological profile correlated with a significant decrease in cell proliferation and induction of apoptosis at 3 and 5 mM. Further studies confirmed that all ASA isomers dose-dependently induced a cell cycle arrest in HT-29 cells, producing an increased percentage of cells in the G$_0$/G$_1$ phase, relative to the population of cells in the untreated control. In this regard, we did not find any significant difference between ASA isomers, which suggests that the anticancer and chemopreventive effects of acetylsalicylic acids are independent from the relative position of COOH and COCH$_3$ moieties in the pharmacophore.
In conclusion, the observed structure-activity relationships among ASA isomers, suggests that \textit{m}-ASA and \textit{p}-ASA should be considered equivalent to aspirin from a pharmacological point of view, because despite differences observed in the in vitro assays, all ASA isomers decreased PGE$_2$ levels to the same extent in vivo. Moreover, the marked similarities in the synthesis of MDA, expression of TNF$\alpha$, and inhibition of antioxidant SOD in gastric tissue, there is a significant difference between different ASA isomers in their ability to produce gastric ulcers when administered orally, which warrants further studies to explore the potential use of relatively safer ASA analogues possessing either a \textit{meta-} or \textit{para-} relationship between the COOH and COCH$_3$ moieties.

Figure 1: Chemical Structures of positional isomers of aspirin.

Figure 2: Effects of positional isomers of aspirin on gastric PGE$_2$ level, lipid peroxidation (MDA), superoxide dismutase (SOD), and plasma TNF-α. Four groups of rats were treated with vehicle, o-ASA, m-ASA, and p-ASA and their stomachs removed and processed as described in Methods. All three drugs caused a significant reduction in gastric mucosal PGE$_2$ levels (panel A). Results are mean ± SEM of 5 rats in each group, *$P < 0.01$ vs vehicle group. All 3 compounds caused an almost 6-fold increase in MDA levels, (panel B). Results are mean ± SEM for 5 rats in each group, †$P < 0.01$ vs vehicle group. All 3 compounds caused a significant reduction in SOD activity (panel C). Results are mean ± SEM of 5 rats, *$P < 0.05$ vs vehicle group. All 3 compounds caused a significant rise in plasma TNF-α, (panel D). Results are mean ± SEM for 3 rats in each group, *$P < 0.01$ vs vehicle.

Figure 3: Positional isomers of aspirin inhibit the growth of HT-29 human colon cancer cells. Cells were treated with various concentrations of o- m- p-ASA as described in Methods. Cell numbers were determined at 24 h. The IC$_{50}$ for cell growth inhibition was > 5 mM for all 3 positional isomers of ASA, however, p-ASA was significantly more potent than the o- and m-isomer at all concentrations. Results represent means ± SEM of three different experiments performed in triplicate. *$P < 0.05$ vs o-ASA and m-ASA.

Figure 4: Positional isomers of aspirin induce apoptosis and inhibits proliferation of HT-29 cells. Cells were treated with o-ASA, m-ASA, or p-ASA at the concentration indicated for 24 hr after which the cells were stained with annexin and propidium iodide and subjected to flow cytometric analysis as described in Methods. The percentage of apoptotic cells increased in a concentration dependent manner (Panel A). Panel B, cells were treated with o-ASA, m-ASA, or
p-ASA at the concentrations indicated for 24 h after which PCNA expression was determined by flow cytometry and expressed as percentage positive cells as described in Methods. Results are mean ± SEM of three different experiments. *P < 0.05 compared with untreated cells.

Figure 5: Effects of positional isomers of aspirin on cell cycle in HT-29 cells. Cells were treated for 24 h with various concentrations of o-ASA, m-ASA, or p-ASA, and their cell cycle phase distribution was determined by flow cytometry, as described under Methods. Results are representative of two different experiments. This study was repeated twice generating results within 10% of those presented here.

Figure 6: m-ASA and p-ASA cause less gastric damage compared to o-ASA. Drugs were administered orally at equimolar doses (1 mmol/kg) and effects on the stomach were evaluated as indicated in Methods. o-ASA caused severe gastric damage, UI = 45 ± 3.1 mm, whereas both m-ASA and p-ASA were relatively gastric damage-sparing, UI = 14 ± 3.0 mm and 17 ± 4.1 mm for m-ASA and p-ASA, respectively (panel A). All three drugs also caused erosions of the gastric mucosa, but the damage was less with o-ASA compared to that of m-ASA and p-ASA (panel B). Results are mean ± SEM for 5 rats in each group, *P < 0.05 compared to the vehicle group; †P < 0.05 compared to o-ASA.

Figure 7: Docking of positional isomers of aspirin to the active site of cyclo-oxygenase-1 and -2. Hydrogen atoms are not shown for clarity.
Table 1. Inhibition of COX-1 and COX-2 by positional isomer of aspirin before and after dialysis. Ovine COX-1 or COX-2 were incubated in the presence of \(o\)-ASA, \(m\)-ASA, or \(p\)-ASA together with arachidonic acid and enzyme activity determined before and after microdialysis as detailed in Methods. *\(P < 0.05\) compared to before dialysis; †\(P < 0.05\) compared to \(o\)-ASA at same concentration before dialysis, ‡\(P < 0.05\) compared to \(o\)-ASA at same concentration after dialysis. Results are mean ± SEM for 5-7 different determinations with enzymes assays being done in triplicates.
